From the Editors

This is the eighth year that Current Research in the Pleistocene has been published. Each year we see a voluminous amount of material that needs to get out to each researcher—and this year and volume are no exception. This edition contains 63 articles.

This year we moved the production of CRP to Northern Arizona University. Dave Meltzer and I are trying to streamline the production. We now have the production system designed to make editing and desktop publishing a reality for CRP. However, we now need your help. We need each author who submits a manuscript to follow the CRP style guide. You would be surprised at what we receive in the mail as “camera ready” manuscripts. If you are going to submit a manuscript to us for inclusion into CRP, please FIRST look at this issue of the journal—and then follow its style for your manuscript. Please also look at the style guidelines printed at the back of this issue. There are a few changes from previous years. Most of all please note that you must (should—please) submit your manuscript both in hard copy and on computer disk (Macintosh, MS DOS/IBM, or Apple II format). Your article should be in both the original word processing format, and as an ASCII disk file. The hard copies I will use to make my editing marks and to send out for peer review. The computer disk file is what we will use for the desktop publishing system to input your manuscript. This will save us loads of time, keep the cost of the volume down, and keep your “camera ready” manuscript as clean as you sent it in to us.

Dave Meltzer’s job is to read all archaeological related manuscripts, provide his own review, and determine who should be an outside reviewer for each manuscript. Jim Mead read all manuscripts We also requested the help of Dr. Larry D. Agenbroad and Dr. R. Scott Anderson to help serve as partial reviewers. They read paleontological/geological and ecological manuscripts (respectively) and suggest outside reviewers and provide their own opinions for each manuscript. Dave and Jim want to make CRP a peer reviewed journal, but to keep in touch with the “within a year turnaround time.”.

The word is becoming streamlined—as CRP is trying to do too. In this effort, please follow the 1991 style guidelines, provide us with a computer disk file, and get the manuscripts in early. Remember you can use FAX and BITNET to get in touch with Dave.

The Diring Yuriak site at 61° 12' N and 128° 28' W has yielded good evidence of an early Paleolithic occupation. Mochanov (1988) has directed work at the site since 1982. At his invitation, R. Ackerman, R. Carlson and M. Carlson visited the excavations, Aug. 14-17, 1990, and spent an additional day examining artifacts. The following report is a summary of our observations. The site is situated on the right bank of the Lena River, overlooking a small stream-cut valley (Diring Yuriak), and about 140 km upriver from Yakutsk. At this location, a series of terraces at 10, 70, 90, 105-120, 125-135, and 140-165 m above the Lena have been investigated. The upper terraces from 105-165 m are composed of a series of alluvial/aeolian deposits over a Cambrian limestone formation (Tabagin Terrace). During the excavation of late Neolithic burials, S. Fedoseeva and I. Mochanov discovered a few artifacts of the Diuktai culture and below these a number of broken quartzite cobbles and spalls.

Trenches were then cut across the upper three terraces to determine the site stratigraphy and extensive horizontal excavation was undertaken by bulldozer to expose the underlying cultural horizons. The stratigraphic sequence (by layers) is: (1) Cambrian limestone, (2) sand and quartzite cobbles (source of raw materials used for tools), (3) a distinctive horizon of red, cross-bedded, alluvial sand, (4) sand-filled frost or desiccation wedges in the top of layer 3, (5) artifacts and concentrations of lithic debitage in a deflated sandy zone, and (6-16) layers of sand, sandy loam, and loam with some intermixing due to solifluction. Bore holes on the 125-135 and 140-165 m terraces revealed that layer 5 is 15-40 m below the present surface. The entire depositional sequence was distinct and uncomplicated.

R. E. Ackerman, Department of Anthropology, Washington State University, Pullman, WA 99164-4910.

R. L. Carlson, Simon Fraser University, BC Canada.
The lithic materials from layer 5 are clearly artifacts. They occur most frequently in concentrations around a large cobble anvil. Isolated artifacts are uncommon. Impact scars from unsuccessful attempts at fracturing are present on some specimens and many flakes can be refitted to core remnants. Most specimens are classifiable as cores and unmodified flakes and a lesser number as unifacial pebble choppers, core scrapers, and scraper-planes. More advanced tool types are absent. Quartzite is the common raw material. Most specimens show evidence of heavy abrasion by blowing sand. Overall, the most economical interpretation of the site is that it was occupied at a time when the level of Lena River was at the height of the Tabagin terrace and the cultural assemblage is the result of localized lithic reduction along the shore.

We also visited a small excavation (6 by 6 m) on the Tabagin terrace overlooking the mouth of the Buotomo River, 20 km downstream from the Diring site. The cultural deposit consisted of the same quartzite industry—cores, flakes and anvils, but was only 20-30 cm below the present surface and the artifacts appeared to be less sand blasted. The associated soil matrix was a light colored sand underlain by the layer of red sand as at the Diring site. Thirteen additional sites of this complex have been located, but not excavated.

Paleomagnetic age estimates on the layers above and below layer 5 date it between 3.2 and 1.8 million years ago. TL dates on samples sent by Mochanov to the Laboratory of Radiotheroluminscent Dating at the University of Moscow provided the following: layer 4—more than 1.8 Ma [RTHL 454], layer 6—2.9±0.96 Ma [RTHL 424] and more than 1.1 Ma [RTHL 453], layer 15—2,000±1,000 yr B.P. [RTHL 439] and layer 16—7,000±3,500 yr B.P. [RTHL 434]. Implications of the occurrence of human settlement at 61°N at 2-3 Ma on currently accepted models of human evolution have provoked considerable controversy among Soviet scientists. In a discussion with geologist O. V. Grinenko of the Yakut Institute of Geological Sciences, who headed a geological congress which met at the site three weeks before our visit, it was clear that none of the visiting geologists would accept a date earlier than 500,000 yr B.P. and that many felt that layer 5 could be much younger. Further dating of the site by independent agencies is needed.

The Diring Yuriak complex is significant for New World prehistory because of its unspecialized technology, early geological context, general proximity to Bering Strait, and the inferred early arctic adaptation of its occupants. It is the type of complex that fits into models of a very early pre-Clovis occupation of the New World. While we do not believe that any of the proposed pre-14,000 B.P. sites or complexes in the New World can be accepted as unequivocal evidence of such an occupation, the Diring site is a potential ancestor for any that may eventually be validated or that future research may bring to light.

Folsom Landuse Patterns in the Southern Tularosa Basin

Daniel S. Amick

Surveys of large land tracts on the Fort Bliss Military Installation have produced a significant record of Folsom landuse patterns in the southern Tularosa Basin. Systematic surface survey has been conducted on nearly 1500 square km within the Fort Bliss maneuver areas (Whalen 1977, 1978; DeGarmo 1983; Carmichael 1986). Numerous prehistoric occupations including 5 Folsom sites and 39 isolates have been recorded in this Chihuahuan desert grassland located between El Paso, TX and Orogrande, NM (Krone 1975; Whalen 1978; Carmichael 1986). The Fort Bliss Folsom collections were recently studied to investigate regional patterns of artifact distribution.

The occurrence of Folsom artifacts near El Paso has been discussed by numerous local avocational archaeologists (Quimby and Brook 1967; Brook 1968; Russell 1968; Davis 1975; Krone 1975). Concentrations of Folsom artifacts are reported within the central portion of the Tularosa Basin north and east of Fort Bliss. These localities are often associated with playas and prominent landmarks. Wimberly (1973) has briefly described the Lone Butte site assemblage which may represent a series of Folsom killsites and camps. However, similar Folsom camps with high artifact densities have not yet been found at Fort Bliss. Nonetheless, there does appear to be geographic patterning within the Fort Bliss data which contributes to understanding regional Folsom landuse patterns.

Judge and Dawson (1972; Judge 1973) have presented a model of Paleoindian settlement technology in the central Rio Grande Valley. The data from the southern Tularosa Basin expand our knowledge about Folsom landuse in environments that lie southwest of the Great Plains. Unfortunately, all of the Folsom artifacts from Fort Bliss are isolates or mixed with later components. Consequently, this study has focused on comparing the distribution of Folsom and Midland projectile points and preforms only. This assemblage includes 3 Midland points, 40 Folsom points, and 22 Folsom preforms.

The use of local raw materials for tool manufacture predominates within the Fort Bliss Folsom collections. A variety of cherts and altered metamorphic and volcanic rocks occur in the surrounding mountains (Banks 1990). The alluvial fans along the margins of the basin contain chert, chalcedony, and obsidian.

Davie! S. Amick, Quaternary Sciences Center, Desert Research Institute, P.O. Box 60220, Reno, NV 89506.
originating from the mountains and the ancient Rio Grande axial gravels. The basin floor lacks significant sources of toolstone.

The isolates consist of 2 Midland points, 27 Folsom points and 4 preforms. Isolated points are commonly distal fragments or complete points (n=21, 60%) which suggests that Folsom isolates represent gear that was broken or lost while hunting. About 83% (n=29) of the isolated points exhibit impact damage. The ratio of points to preforms among the isolates is 6.80 (34:5) which is at least four times higher than site assemblages in the central Rio Grande Valley (Judge 1973). The high incidence of isolated Folsom points and distal fragments, impact damage, and points to preforms indicates a pattern of dispersed hunting activities. Manufacture of points and replacement of hunting gear does not appear to have occurred in the field.

Folsom sites are defined as discrete localities where two or more of these artifacts were found. The high proportion of basal point fragments (n=13, 68%) in the site assemblages suggests that repair of broken hunting gear was conducted at camps. All of these basal fragments exhibit impact damage which implies that they were bound within a foreshaft that was usually retrieved and returned to camp. The broken point fragments were then removed from the foreshaft and discarded. Site assemblages exhibit a point to preform ratio of 1.0 (19:19) indicating that manufacture of replacement points also occurred at the camps.

Unfortunately, interassemblage variation among the Folsom collections from the Tularosa Basin is poorly documented. However, the Dona Ana Folsom Camp (FB-1613) located in Fillmore Gap between the Franklin and Organ Mountains contains a relatively large and functionally distinctive assemblage. FB-1613 is situated near a low mountain pass (ca. 1278 m elevation), about 60 m above the Tularosa Basin floor. This location confers numerous strategic advantages: lithic resources, a nearby playa, access to mountain resources, passage into the Rio Grande Valley, and a landscape overview. Recent excavations by Dr. Mark Stiger have produced an assemblage dominated by tool manufacturing debris. The ratio of points to preforms at FB-1613 is 0.40 (6:15) which is less than the average from Judge’s armament sites (0.48). While Folsom groups may have occupied the FB-1613 locality for various reasons, toolstone procurement and preform manufacture were particularly important activities at this low mountain pass location.

Thanks to Raymond Mauldin and Dr. Glen DeGarmo at the Environmental Management Office, Directorate of Installation Support, Fort Bliss for assisting this research.

Paleoindian Occupation Greater than 11,000 yr B.P. at Tule Lake, Northern California

John M. Beaton

Recent test excavations in rockshelter deposits on the western shores of Tule Lake, Siskyou County, California indicate an occupation history dating to at least 11,450±340 yr B.P. (Beta-39545). The ¹⁴C determination was made on a sample of burned wood charcoal from a small fire pit excavated at -215 to -220
cm below the surface of the shelter deposit. The date is interpreted to indicate the age of an anthropogenic cooking or warming fire which marks an incident of shelter use by Paleoindian foragers who were exploiting the lakeshore/marsh resources of Tule Lake.

Modern Tule Lake, which sits adjacent to the California-Oregon border is a shallow remnant of Pleistocene Tule Lake, which was one of a complex of extensive marshlands associated with the Klamath River, its tributaries and distributaries east of the Cascade Range. The area shares biogeographic (and ethnographic/ethnohistorical) elements with the plateau region to the north, the basin and range province to the east, and riverine-montane California province to the west and south. Earlier archaeological work in the area includes the Lower Klamath lake studies of Cressman (1942) and McGuire (n.d.). Grayson (1973, 1976) has done extensive studies of the Lower Klamath archaeofauna. While these studies have clearly indicated the importance of wetlands to foragers of the Holocene, and the likelihood of earlier occupations, no 14C dates have been obtained which would suggest occupations earlier than ca. 7,000 years ago. As part of a research program into the “colonization” (i.e. strategic selection) of lakeside-marsh habitats by foragers, a small crew from University of California, Davis sampled selected rockshelter sites at Tule Lake in 1989 and 1990.

The archaeological sites along the western shore include approximately 15 sheltered deposits and a similar number of surface indications (Squier and Grosscup n.d.) of forager activity. The archaeological site (Ca-Sis-218) from which the comparatively early date was taken is situated at the foot of a basalt cliff which overlooks the western shore of the lake, well above Holocene lake levels. This site was chosen for preliminary testing because it satisfied several research considerations, including (1) its close association to lakeshore and marsh resources of the Pleistocene and Holocene, (2) its apparently high rate of sediment accumulation (and therefore potentially good chronostratigraphic separation), (3) its sheltered micro-environment, and (4) its evident lack of disturbance or post-depositional turbing.

Test excavations, amounting to approximately 10 m$^3$, differentially sampled the somewhat more than 2 m deep deposit, with only slightly more than two cubic meters having been excavated from below -1.0 m. Upper levels in the site were comprised of an expectable stratigraphic record in which Gunther series projectile points were succeeded by small sidenotched varieties. Milling equipment occurred in upper levels of the site and one mano-like muller with clear evidence of ochre pigment grinding was recovered from -110 cm. This implement may be associated with petroglyphy, some of which is in evidence on the walls of shelters on the lakeshore.

The date reported here is the first from the site. It was collected as part of a small feature, a fire-pit at -210 cm. The small fire pit was ca. 18 cm in diameter and had a maximum thickness of 5 cm. It was comprised of ash, small fragments of burned wood, and the heavily degraded bones of fish. In close horizontal proximity to this feature were found chips of obsidian, high quality silicious toolstone chips, and a single unifacial base.
Although bifacially worked pieces, including apparent mid-sections of knives or points occurred in stratigraphic association with the dated feature, no potentially time-diagnostic pieces were recovered.

Importantly, sediments containing the 11,450 yr B.P. date estimation overlay approximately 20 cm of cultural deposit which, in our small sample, lacked easily datable features. However, the lowest sediments (-220 to -240 cm) contained artifacts including bone tools, bifacially worked pieces and flaking debitage which were associated with fragmentary bones of fish, birds and mammals. These attest to further and possibly somewhat older cultural deposits. Attempts to accurately date this lower part of the deposit are planned.

Although the research program is in its early stages, preliminary results suggest that fish and waterfowl, rather than terrestrial fauna, were the important flesh elements in this early forager diet. On first indications, the shelter deposits do not suggest large sedentary occupations, but rather the periodic use by small lakeshore-focused groups which employed economic strategies directed toward the taking of fish and waterfowl. Further analyses of recently excavated material, and additional work at this site, and at other nearby sites, are planned.

This research was sponsored by a University of California, Davis, Faculty Research Grant D-2068. Additional support was received from the Bureau of Reclamation (Grant No. 9-FG-20-08800). Permission to excavate was granted by the US Department of Fish and Wildlife. I particularly thank my UCD students for their effort, G.J. West (Bureau of Reclamation) and Anan Raymond (USFWS) for encouragement, and J. F. O'Connell for introducing me to the archaeology of northeastern California.

The Johnson Site: A Dated Clovis-Cumberland Occupation in Tennessee

John B. Broster, David P. Johnson, and Mark R. Norton

The Johnson site (40Dv400) was recorded as part of the Tennessee Division of Archaeology's continuing state-wide Paleoindian site survey (Broster 1989; Broster and Norton 1990). The site is a large multi-component habitation located on the Cumberland River in East Nashville. It was first observed as a dense scatter of lithic materials on the edge of the river (at low pool). Projectile points, bifaces, preforms, unifacial tools, and a high density of bifacial reduction flakes were noted. Diagnostic artifacts which were recovered included three Clovis preforms and the following projectile point/knife types (number of specimens): Cumberland (3), Dalton (1), Harpeth River (3), Greenbrier (2), LeCroy (2), Kirk Serrated (6), and Kirk Corner-Notched (51).

A series of dark, culturally derived lenses can be observed in the riverbank. There appears to be at least four major occupations represented. Ranging in depth from the surface to approximately 50 cm below surface are materials affiliated with the Mississippian period (500 to 950 yr B.P.). This occupation is represented by a very sparse scatter of lithic and ceramic artifacts (six sherds and one projectile point).

At 3 to 4 m below surface there is a thin stratum of burned sandy clay and charcoal which produced MacCorkle Stemmed and LeCroy projectile points. These types have been dated in the Little Tennessee River valley at between 8,000 and 9,000 yr B.P. (Chapman 1976; Broyles 1971).

Directly below this component at a depth of 5 to 6 m below surface is a dark, organically stained, silty clay level containing Kirk Corner-Notched projectile points and numerous fragmented bifaces. The level seems to have a downward slant toward the west and ranges from 10 to 40 cm in thickness. Kirk Corner-Notched points have been dated on the Little Tennessee River at between 8,900 and 9,600 yr B.P. (Chapman 1976; Chapman 1977).

A fourth cultural level is located at 20 to 30 cm below the Early Archaic occupation. The deposit varies from 50 to 96 cm in thickness, and the top of the stratum measures approximately 6.5 to 8.0 m below the ground surface. At this preliminary stage of investigation, no internal stratigraphy has been observed within the level.

A shallow basin feature, with a slightly rounded bottom, is evident in the upper level of this deposit. The basin is 33 cm deep and 62 cm wide, with the
upper 20 cm characterized by a light brown silty clay with sparse lithics. The bottom 13 cm consist of a dark gray ash mixed with charcoal, burned bone, and numerous bifacial reduction flakes. A carbon sample was taken from the feature, and profile drawings constructed. It was felt that the majority of the feature should be left intact for future study. The date produced from this feature was 12,660±970 yr B.P. (Tx-6999). It is believed that there is very little chance of sample contamination, however, future plans call for complete excavation of this possible hearth to obtain an additional sample(s) for dating.

Another carbon sample was taken from the lower portion of the same level about 20 m to the west of the feature. The sample was taken 30 cm from a Clovis preform which was cemented in the brown silty matrix. A date of 11,700±980 yr B.P. (Tx-7000) was obtained. Below the location where this sample was taken (near river’s edge), a Cumberland projectile point, two Clovis preforms, and a unifacial scraper were recovered. Unfortunately, these specimens were located out of context, but probably had washed down from the dated deposit (Figure 1).

These cultural deposits are being constantly eroded by the river and it is feared that much of the site has already been washed away. Due to the infrequent location of intact Paleoindian components, it is felt that this site is extremely important to our understanding of Paleoindian occupation in the Central Basin of Tennessee. The Division of Archaeology proposes further fieldwork in 1991 in hope that a series of dates can be run from the levels containing Paleoindian and Early Archaic deposits. Two additional sites on the Cumberland River have been reported which may have the potential for yielding comparable dates. The Division of Archaeology will also be undertaking research on these sites during the next field season.

Figure 1 was drawn by Gary Barker.

Clovis and Cumberland Sites in the Kentucky Lake Region

John B. Broster, Mark R. Norton, and Richard Anderson

The Kentucky Lake region, which forms the boundary between west and middle Tennessee, has been known to produce large numbers of fluted Paleoindian projectile points and uniface tools. Local collectors have kindly made their points available for study over the years. Additionally, the Nuckolls site (40Hs60) was extensively tested by archaeologists from the University of Tennessee in the late 1950s (Nuckolls 1958; Lewis and Kneberg 1958). The Nuckolls site has produced at least 13 Clovis, 6 Cumberlands, and 1 Redstone, as well as Beaver Lake, Quad, and Dalton projectile points.

We decided to concentrate our survey efforts in the lake district, due to this past history of investigations and the availability of collections for study. Prior to our research of the last season, only nine archaeological sites from the lake area were known to have produced significant Paleoindian assemblages. Our examinations have added 14 sites to the state survey files. Of these sites, 12 have fluted point components (Clovis, Cumberland, and Redstone). The number of fluted points is rather low as compared to the numbers for late Paleoindian and early Archaic from the same sites. Whether this represents an increase in population or some other cultural process remains an open question at this stage of research.

A total of 85 Clovis, 28 Cumberland, and 2 Redstone have been documented on 12 of the 23 Paleoindian sites from the region. Within these same sites, metric data has been obtained from 864 late Paleoindian projectile points (122 Beaver Lakes, 39 Quads, 244 Daltons, 72 Harpeth Rivers, 384 Greenbriers) and 27 late Paleoindian preforms. Two Clovis, four Cumberlands, and seven late Paleoindian projectile points were recorded as isolated finds (see Figure 1).

Three of the newly recorded sites have also produced large numbers (+100 per site) of uniface tools. Unfortunately, these sites are all highly deflated by wave action, making it nearly impossible to distinguish between fluted and later Paleoindian assemblages. A local variety of Dover chert constitutes some 85 to 95% of all lithic raw materials on these sites. Potential quarry pits (40Hs202) have been recorded on the eastern bank of the lake in proximity to the old Tennessee River channel. The material from these quarries is the same high quality Dover chert as is found on the Paleoindian sites.

Occupation during the Clovis and later Cumberland times appears to be represented by light to moderate scatters of lithic materials, with numerous fluted preforms being recognized on most of the sites. Tool manufacture and maintenance of hunting equipment are suggested as very important functions for the early occupations. The number of large uniface knives and sidescrapers probably denote some butchering activities taking place on the sites. The fluted point sites are located on the mouths of tributary streams on well drained terrace remnants adjacent to the old Tennessee River channel. These maintenance/manufacturing camps are possibly associated with kill and butchering sites located at lower elevations along the old channel. Unfortunately, such sites, if they exist, are covered by some 13 to 16 m of water.

Before the creation of the lake, these Paleoindian site locations were generally situated at relative short distances from low swampy areas. The locations on major river terraces would have provided Paleoindians with relatively dry elevated areas proximate to probable watering and fording localities for large herd animals. Aquatic resources may also have been important in these locations.

Several hundred artifacts are presently being measured and studied. Reports are being prepared on two of the more extensively occupied sites, 40Hs23 and 40Hs200. Both sites contain Clovis and Cumberland, late Paleoindian, and early Archaic components. A third site, 40Hs173, has been tested and a report will soon be published (Broster and Norton 1990).

It is hoped that this large body of information will be useful in understanding changes from early to later Paleoindian occupations, and as important to the study of the dramatic differences in projectile point styles between the Paleoindian and the early Archaic. Our objective has been to document metric and raw material data from the numerous collections from the region, and to generate accurate provenience determinations for the materials. We have been very fortunate to work with a supportive group of private citizens and amateur archaeologists, and any progress made has been due to their help and encouragement. We plan to continue the recording of collections and site locations for several more years, with the ultimate goal of providing a
solid data base for future researchers interested in the Clovis and later Paleoindian occupations of Tennessee.

Figure 1 was drawn by Gary Barker.

Engraved Cobbles from Early Archaeological Contexts in Central Texas

Michael B. Collins, Thomas R. Hester, David Olmstead, and Pamela J. Headrick

Site 41BL323 in southernmost Bell County, Central Texas, has been the subject of attention intermittently for at least 62 years. It was first trenched by Dr. J. E. Pearce of the University of Texas in 1929 (who dubbed it the Gault Site and believed it to be in Williamson County). Since then, parts of the site have been dug by relic collectors, especially since 1980. Digging by the latter has revealed dense archaeological remains more or less continuously over an area roughly 700 by 200 m. Branches of upper Buttermilk Creek transect the site; permanent springs and seeps feed the creeks at the locality. Most digging has concentrated on the dense midden deposits of early Archaic to late Prehistoric age, but a significant number of artifacts with Paleoindian affiliation have been found (projectile points classifiable as Clovis, Plainview, Folsom, Midland, Hell Gap, Scottsbluff, Angostura, and possibly Golondrina). Over most of the site, these materials are found from the surface to depths of 1.5 m or less. Extensive outcrops of high quality Edwards chert and protective bluffs, in addition to the springs, were probably important factors in the prehistoric uses of the locality.

In one area of the site, digging to a depth of ca. 2.5 m has revealed complex stratigraphy and brought to light at least 4 Clovis points, 10 engraved cobbles, a retouched flake of quartz crystal and numerous chert objects (including cores, flakes, blades, bifacial preforms, a burin spall, fragmentary bifaces, and a unifacial Clear Fork tool). One of us (DO) found two of the engraved cobbles (Figure 1c) with one of the Clovis points (Figure 1b) sandwiched between them. No controlled excavation has yet been conducted in this area of the site and the full context of this find is unknown. Two of us (MBC and TRH) recovered four engraved cobbles from backdirt in this area of the site (Figure 1e). The setting, stratigraphy, and some of the materials recovered in this area of the site are the subject of this note.

The intriguing finds discussed here were made in a restricted area where springs emanate from the base of the valley wall. A thin, transitional Archaic to late Prehistoric midden overlies multiple, interstratified lenses of (1) colluvial, (2) valley fill, and (3) spring deposits, respectively of (1) irregular pebbles to boulders of limestone, (2) silts, sands, and clays, and (3) tufa. A
calcium carbonate cement separates the base of the midden from underlying deposits. Plainview, Scottsbluff and other early artifact forms occur in conjunction with the calcium carbonate, suggesting that underlying deposits may be earliest Holocene to latest Pleistocene in age. It was from the deepest penetrated lens (apparently of valley alluvium) that the four Clovis points and 10 engraved stones are believed to have originated. We have closely examined only two of the Clovis points.

The larger Clovis point of these two (Figure 1a) is of grayish-tan, patinated (Edwards?) chert, measures 88 by 31 by 9 mm and has recurvate lateral edges. The smaller (Figure 1b), which was found nested between two engraved stones,
is of Alibates chert, measures 57 by 33 by 10 mm and has been heavily resharpened.

The 10 engraved stones are all smooth limestone pebbles and cobbles ranging in length from 4.5 to 16.0 cm. Two are broken. Two are engraved bifacially. The engraving consists of fine lines evidently produced with a sharp-edged flake. Straight lines predominate. On four stones, parallel line sets intersect similar sets at various angles to form rectilinear or diamond-shaped grids (Figure 1c, e). Complex patterns of intersecting straight and curving lines dominate on two stones; an animal is depicted as part of one of these. One stone (Figure 1d) has diamond-shaped motifs at the ends of straight lines. Three stones are either too eroded or too carbonate-encrusted for adequate viewing of the engraved patterns.

On the basis of very limited evidence, these engraved stones seem to occur in the same depositional unit as four Clovis points, the only diagnostics found there to date. This unit is well below the calcium carbonate cap which seems to be of very early Holocene age; however, given the presence of active springs, mixing may be a factor in the apparent associations. A controlled excavation is being planned under the auspices of the Texas Archeological Research Laboratory to more fully investigate these occurrences.

At the Wilson-Leonard Site (41WM235), 40 km southwest of the Gault Site, a large chert flake with a rectilinear grid engraved on its cortical exterior in a pattern like that illustrated here (Figure 1c, e) was found in the deepest cultural zone in association with Midland points.

Casts of six of the specimens have been made possible in part by a grant to Hester from the University Research Institute at the University of Texas at Austin. We also thank Mr. Elmer Lindsey for permission to visit the site. Gratitude is also expressed to Pete Bostrom, Troy, IL, for bringing the materials to Hester's attention. Dr. Frank A. Weir of the Texas State Department of Highways and Public Transportation is thanked for permission to cite the Wilson-Leonard find.

Paleoindian Component at the Linn Woods Site, Sussex County, Delaware

Jay F. Custer and Glen Mellin

The Linn Woods Site is located in the Coastal Plain of southern Delaware on a low knoll overlooking an extensive estuarine marsh complex in the Indian River drainage. Application of local sea level rise curves, soils data, and pollen data indicate that during late Pleistocene times the site was located adjacent to freshwater wetlands within a pine-spruce forest setting.

---

Jay F. Custer and Glen Mellin, Center for Archaeological Research, Department of Anthropology, University of Delaware, Newark, DE 19716.
Spatial distribution of artifacts at the site indicate two activity areas. One is a cobble reduction area consisting of a debitage concentration over an area of nine square meters. The second activity area consists of a very light artifact scatter extending over 21 m$^2$ adjacent to the cobble reduction area. The bifaces and core were found within this light artifact scatter and the second activity area probably represents a general habitation/work area distinct from the core reduction area.

The Paleoindian occupation at Linn Woods seems to represent a transient camp at which tool kits were refurbished using local cryptocrystalline cobbles. The presence of a multi-function flake tool and projectile points suggests processing of game animal and plant resources from the local wetlands. The use of Paleoindian sites with low knolls near interior freshwater wetlands shown by the Linn Woods Site are patterns of Paleoindian adaptations seen at a number of sites on the Delmarva Peninsula (Custer 1989; Lowery 1989; Lowery and Custer 1990).

Reappraisal of the MacHaffie Site Paleoindian Occupational Sequence

Leslie B. Davis, John P. Albanese, Linda Scott Cummings, and John W. Fisher, Jr.

Archaeological excavations in 1951 at the famous MacHaffie (24JF4) Paleoindian open-air campsite, southeast of Helena, Montana, documented stratified, in situ Folsom and Cody (Scottsbluff) complex occupations (Forbis and Sperry 1952). The site had been occupied intermittently from early

John W. Fisher, Jr., Department of Sociology, Montana State University, Bozeman, MT 59717.
Paleoindian to late Middle Period times. In the decades following excavation, the small, culture-bearing peninsula had been severely vandalized, raising doubt concerning site survival. The original MacHaffie artifact and faunal collections were not available for detailed follow-up study.

The MacHaffie site assessment project was initiated in 1989 by three weeks of summer excavation, followed by month-long excavation in 1990. Fieldwork was guided by four objectives: a) to test for extant Paleoindian deposits; b) to perform geoarchaeological studies and detailed pollen and phytolith analyses to permit reconstruction of local paleoecology; c) to obtain and radiocarbon date in situ organic samples from recognized cultural strata; and d) to obtain artifacts and ecofacts from each discerned cultural stratum for analysis and Museum interpretation.

The MacHaffie site is situated on the northwest flank of the Elkhorn Mountains, a major, northwest to northeast trending range composed largely of intrusive and extrusive igneous rocks of Cretaceous age. The site, at an elevation of ±1,280 m, is contained within the center of the narrow alluvial floor of a northwest draining, spring-fed, ephemeral stream valley, tributary to Prickly Pear Creek from the east. In 1989, a 13.0 m long, ±2.3 m deep trench was emplaced across this non-eroded “island”, just upgrade from the original excavation area. The basal 1.2 m thick alluvial unit contains three A-C horizons; the early Holocene was evidently a time of geomorphic stability. Evidence for four Paleoindian occupational events is enveloped within specific alluvial deposits. The upper three are marked by discrete, layered accumulations of lithic and bone detritus. The lowermost, which lacks clear stratification but is traceable in parallel with overlying occupational strata, is contained within a nonpedogenic, micaceous clayey sand and gravel unit of unknown depth.

The affiliations of the four recognized Paleoindian cultural strata are identified provisionally: Stratum I (Folsom ?), Stratum II (Folsom), Stratum III (Scottsbluff ?), and Stratum IV (Scottsbluff). While two broken bifaces were recovered from Stratum I and two broken bifaces were found in Stratum IV (one steeply marginally retouched flake, and one elongate end scraper with a graver-type spur), the only diagnostic recovered during both seasons is a chalcedony channel flake from Stratum II. Locally quarried chert and chalcedony dominate these lithic assemblages. The section through the peninsula, sampled in 1989 and expanded along the south bank in 1990, is considerably thicker, at ±2.3 m, than the originally excavated section adjacent but downslope to the west. The increased depth of the section at that upgrade location probably explains stratigraphic separation and the doubling of culture-stratigraphic entities indicated by current research.

Analysis of pollen samples recovered in 1989 from the entire section indicate that sagebrush (Artemisia) steppe predominated in this locality throughout the Holocene. The valley floor itself was covered by riparian vegetation prior to ca. 8,280 yr B.P. Increases in sagebrush pollen immediately thereafter mark the onset of mid-Holocene Altithermal conditions. At an as yet undated
interval within the overlying colluvial unit, an explosive increase of pine (Pinus sp.) pollen records the onset of Medithermal conditions.

MacHaffie Stratum II yielded small amounts of fragmentary, unidentifiable bones, and a first phalanx from a large canid (Canis sp., cf. Canis lupus). Stratum IV yielded the proximal end of a shed deer (Odocoileus sp.) antler and forelimb and hindlimb bones of a minimum of one bison (Bison sp.). The size of the bison bones compares favorably with adult male bison from Cody complex sites such as Horner (48PA29) (Todd 1987) and Finley (48SW5) (Bedord 1974) in Wyoming. Horner site bison are identified as Bison sp., cf. B. antiquus (Walker 1987). The absence of axial elements suggests selective use of carcass parts, while cut marks and probable impact scars (hammerstone) present on several long bones indicate meat removal and probable marrow extraction.

$^{13}$C/$^{12}$C corrected radiocarbon ages were obtained on archaeological bone and carbonized wood samples collected in 1989 from specific cultural provenances within the profile at the south end of the trench: unidentifiable, unburned bone from Stratum I, 9,340±120 yr B.P. on apatite carbon (GX-15150-A-AMS); unburned bone scraps from Stratum II, 9,130±550 yr B.P. on apatite carbon (GX-15151-A) and 9,000±130 yr B.P. on bone collagen (GX-15151-G-AMS); wood charcoal flecks from Stratum III, 8,620±200 yr B.P. (GX-15152-AMS); and part of an unburned Bison sp. vertebral process from Stratum IV, 8,280±120 yr B.P. on bone collagen (GX-15153-G-AMS) and 7,905±435 yr B.P. on apatite carbon (GX-15153-A). The original solid carbon method age obtained from carbonized wood, of 8,100±300 yr B.P. (L-578A) for the Scottsbluff stratum (Forbis 1962), is consistent with the Stratum IV AMS ages.

The re-dating of Stratum II, using charcoal extracted from carbonaceous sediments in 1990 in order to test the low magnitude of the AMS age, yielded an (unacceptable) age of 8,019±136 yr B.P. (UGA-6309). A $^{13}$C/$^{12}$C radiocarbon age obtained from charcoal particles contained in carbonaceous sediments of Stratum III in 1990, of 8,403±109 yr B.P. (UGA-6307), effectively corroborates the age of 8,620 yr B.P. previously determined for that occupation.

The radiocarbon age series for the MacHaffie Paleoindian horizons is overall systematically younger than expected, although the relative time-stratigraphic order test is met by that array. The Stratum II (Folsom) ages of 9,130 and 9,000 yr B.P. are significantly too recent, given established precedent. However, the possibility that MacHaffie Folsom is that recent is supported indirectly by the apparent lengthening of Folsom complex duration, as hinted by ages of 9,950 and 9,770 yr B.P. reported for Folsom at the Rattlesnake Pass site (48CR4520) in south-central Wyoming (and elsewhere as recent as 10,060 yr B.P.) (Smith and McNees 1990). A possibly relevant age of 9,380±110 yr B.P. (TO-1097) was obtained on seeds from a silty clay zone below the Cody complex bone bed (Bison sp.) at the Fletcher site (DjOW-1) in southern Alberta (Vickers and Beaudoin 1989). That age is equivalent to the 9,340 yr B.P. age for Stratum I below the Cody complex occupation or occupations at MacHaffie. Given the MacHaffie situation, the overlying Cody stratum at Fletcher may not be as old as may be expected. In any case, efforts to establish an accurate radiocarbon chronology for the MacHaffie Paleoindian occupations, by testing for local
contaminants and the fine-grained collection and dating of additional organic samples, and to recover diagnostic artifacts will continue in 1991.

Ongoing research at MacHaffie, one of several "First Montanans Search Program" Paleoindian projects underway, is funded by the Kokopelli Archaeological Research Fund administered by the MSU Foundation and was also supported by the Office of the President and the Office of the Vice President for Research at Montana State University. We are also grateful to Pamela Bompart, property owner, for permitting research access to this important National Register heritage site.

The Lake Chapala First Mexicans Project

Jalisco, Mexico

Shawn D. Haley and Federico Solórzano

The search for the New World's first immigrants is often guided by tantalizing clues and teasing circumstantial evidence (Lynch 1990; Meltzer 1989). The Lake Chapala First Mexicans Project is no different.

Shawn D. Haley, Red Deer College, Box 5005, Red Deer, AB, Canada T4N5H5.

Federico A. Solórzano, Museo Regional De Guadalajara, Instituto Nacional de Antropologia e Historia, Guadalajara, Jalisco, Mexico.
For many years, researchers from Guadalajara aided by local residents have been collecting fossils from in and around the Lake Chapala and Lake Zacoalco basins high in the mountains just south of Guadalajara in the state of Jalisco, Mexico. The collections housed at the University of Guadalajara and the Museo Regional de Guadalajara now consist of over one half million Pleistocene mammalian fossils. The specimens range from tiny fragments to complete skeletal elements and include bear (*Arctodus pristinus*), bison (*Bison* sp.), camel (*Camelops* sp.), capybara (*Nothrocerus*), coyote (*Canis latrans*), deer (*Cervus* sp., *Odocoileus hemionus, O. virginianus*), glyptodon (*Glyptodon* sp.), panothere armadillo (*Holmesina* sp.), horse (*Equus* sp.), jaguar (*Panthera* sp.), llama (*Lama* sp.), mammoth (*Mammuthus* sp.), ground sloth (*Eremotherium* sp.), ground sloth (*Nothrotheriops* sp.), sabertooth (*Smilodon californicus*), wolf (*Canis lupus*) and others. The collection localities which cover several square kilometers are flat seasonally dry clay pans at the lowest elevations of the two internal drainage basins. In all likelihood, the localities contain thanatocoenose (transported death) assemblages. The presence of both mammoth and mastodon as well as numerous late prehistoric artifacts at the same collection locations support that contention.

At the same collection localities, a number of other objects were recovered. They include bone and antler fragments that appear to have been modified by humans into various tool forms (Solórzano 1990). These possible tools were made on bone and antler elements tentatively identified as camel, deer, horse, and mammoth. Also, human skeletal remains, mostly skull and jaw fragments and teeth, were found. They were mineralized to a high degree and highly fragmentary. The mineralization is most interesting in that local variants in ground water minerals shows up in the human remains and mammalian fossils. Both the human and other mammalian fossils from the Chapala Basin are a black to charcoal gray color while those from Zacoalco, a few kilometers to the west, are a muddy brown to gray tan color.

In May 1990, the authors conducted a brief survey of the Chapala/Zacoalco region on the assumption that most if not all of the materials that had been redeposited in the basins were being washed down by the rapid runoffs and flash floods that accompany the annual rainy seasons (May to July). Work began on locating and mapping the remnant Pleistocene Lake Chapala strand lines. Concentrating on the north shore of present day Lake Chapala, Pleistocene beaches were found one to three kilometers from the modern beach. It is likely remnants will be found and recorded in the other quarters as well. We concentrated on these beaches since if humans coexisted with Pleistocene fauna, any remains of that interaction would most likely be located above Pleistocene water levels.

A more controlled survey of the northern shore of Lake Chapala is planned for the 1991 season. The goal is to locate primary deposits, sites that contain evidence of a human presence in western Mexico during the late Pleistocene. It is expected that the First Mexicans Project will take five years to complete and involve a multi-disciplinary team of at least four specialists (one each in archaeology, paleontology, geology, and physical anthropology). In addition
to the archaeological aspect, the First Mexicans Project will focus on the late Pleistocene climate and environment of western Mexico.

The 1991 season will take place between late July and early September. At that point, detailed maps of the Pleistocene beaches will be drawn and artifact and fossil collections described. It is entirely possible that the circumstantial association of Pleistocene fauna and humans will be seen as a spurious one. If that is the case, we will still have learned something. Our hypotheses that humans were present in western Mexico during the late Pleistocene will be rejected but we will have accomplished two goals: 1) we will have gained an understanding of the late Pleistocene climate/environment in that area, and 2) another body of potential First Americans data will have been examined and eliminated from the First Americans inventory. The remaining data can only be the clearer for our efforts.

Early Holocene Archaeological Sites in Mono Basin, East-Central California—Southwestern Nevada

*M. C. Hall*

Recent investigations along the California-Nevada border revealed apparent early Holocene archaeological deposits at two adjacent sites on the northeastern margin of Mono Basin. Situated 13 km east-northeast of the northeastern shore of Mono Lake, CA-MNO-473 and CA-MNO-474 appear to have been first recorded in 1960 by the late E. L. Davis. Whether any artifacts were removed at that time is not known. Surface artifacts are scattered over a 95 by 180 m area at MNO-473, 10 by 45 m at MNO-474. The MNO-473 fieldwork involved 1130 m² of systematic surface collection, and excavations amounting to

M. C. Hall, Far Western Anthropological Research Group, Inc., P.O. Box 413, Davis, CA 95617.
15.7 m$^3$ (24 units, 336 m$^2$); surface collection at MNO-474 encompassed 457 m$^2$ excavations totaling 9.2 m$^3$ (12 units, 28 m$^2$). Select surface artifacts were retrieved outside formal collection units at each site.

Both MNO-473 and MNO-474 sit atop gravelly benches separated by a 60-80 m-wide, 10 m-deep intermittent drainage emanating from uplands immediately to the northeast. These benches represent terraces related to Pleistocene Lake Russell (ancestral Mono Lake) or low-gradient, distal remnants of basin-margin alluvial fans of like age. The two sites lie between 3 m above and 44 m below the variously estimated maximum surface elevation reached by Lake Russell (cf. Gilbert et al. 1968; Lajoie 1968; Mifflin and Wheat 1979; Russell 1889). However, the lack of geochronological data on relict strand lines precludes assessment of local lacustral conditions attending early Holocene human occupations of MNO-473 and MNO-474. Mantling the bench landforms to varying depths are mixtures of tephra, other pyroclastic debris, and eolian-redeposited lacustrine sediments. Though airfall deposits are massive and thick in places, archaeological remains at each site (excepting those associated with two confined historic features) were found mainly in the highly bioturbated eolian/lacustrine sediments that tend to underlie the volcanic strata or resting on lake terrace/alluvial fan gravels wind-stripped of small particles.

Affording chronological perspectives of MNO-473 and MNO-474 are hydration-rind measurements on obsidian artifacts and the recovery from each location of presumed early Holocene projectile point forms. Relevant carbon suitable for radiometric assay was not found at either site. Comprising the latter are Great Basin Stemmed or Western Stemmed (18 at MNO-473, one at MNO-474) and Great Basin Concave-base or Western Clovis (one at MNO-474) types generally attributed ages greater than ca. 7,500 yr B.P. (cf. [among others] Basgall 1988; Carlson 1983; Heizer and Hester 1978; Holmer 1986; Pendleton 1979; Tuohy and Layton 1977; Warren and Phagan 1988; Willig and Aikens 1988). Geochemical analysis distinguished five different kinds of obsidian among the hydration samples drawn (Jackson 1990), sources occurring within 20 to 50 km of the subject sites (cf. Ericson et al. 1976). The MNO-473 sample included 10 pieces of flaking detritus and 9 stemmed points, all yielded hydration values in excess of 7 microns – a measurement threshold surpassed rarely in hydration profiles of obsidian artifacts elsewhere in the Mono Basin region. Briefly, values of 7.7-10.4 microns were obtained for eight specimens of Mt. Hicks geologic origin (four flakes, four points), 7.1-10.4 for six Truman-Queen specimens (four flakes, two points), 8.3-9.3 for two Bodie Hills specimens (points), 9.6-10.1 for two Casa Diablo specimens (flakes), and 10.6 microns for the lone specimen of Glass Mountain material (point). The most reliable hydration rate available for Casa Diablo obsidian (Hall 1984; Hall and Jackson 1989) provides age estimates of 8,100 and 8,800 yr B.P. for the two MNO-473 samples of this glass. While comparable rates are not yet developed for the other obsidians, studies indicate that they are unlikely to be strikingly divergent (Hall 1983; Meighan 1981; Tremaine 1990). This, in turn, suggests ages exceeding seven millennia for the Mt. Hicks, Truman-Queen, Bodie Hills, and
Glass Mountain artifacts from MNO-473. As for the MNO-474 samples, both points from the site (already noted) are made of Casa Diablo glass. Using the rate cited above, hydration values of 9.5 and 9.8 microns for these specimens convert to 7,900 and 8,400 yr B.P. Nine waste flakes from MNO-474 were analyzed as well, the measurements falling between 7.9 and 10.1 microns (glass types: five Truman-Queen, three Mt. hicks, one possible Bodie Hills). Hence, coupled with the stemmed and concave-base points recovered, the MNO-474 hydration data ascribe substantial antiquity to the archaeological remains at this location.

All told, relatively depauperate artifact assemblages were acquired from each site: under 800 items at MNO-473, barely over 150 at MNO-474. Flaked stone dominates both assemblages, consisting primarily of chipping debris (93-94%). Along with the aforementioned projectile points, specific implements from MNO-473 include 11 bifaces, 2 formed flake tools (keeled, scraper-like devices), and 21 simple, or casually modified flake tools; the MNO-474 specimens include 4 bifaces, 3 similar formed flake tools, and 1 simple flake tool. Of note is the fact that the MNO-473 assemblage contains five milling-slab fragments, milling equipment being reportedly an uncommon element in early Holocene archaeological deposits. The meager quantities of material encountered at both sites are consistent with those seen at other early post-glacial localities in the general region, and imply fairly ephemeral episodes of settlement activity. Albeit overall sample sizes are quite limited, hydration measurement ranges leave open the distinct possibility of multiple occupations of each site over a perhaps not inconsiderable span of time. Additionally, obsidian source diversity in the analyzed artifacts bespeaks of geographically wide-ranging land-use systems at the outset of the post-glacial period (cf. Basgall 1989). Much subsurface exploration remains to be done at these Mono Basin sites, particularly since large areas of each are blanketed with thick layers of volcanic airfall. Inasmuch as formal investigation of a clearly early Holocene cultural deposit has been undertaken at only one other location in the region, CA-MNO-679 35 km to the south in Long Valley (Basgall 1988), it is hoped opportunities arise to pursue further the structure, content, and meaning of MNO-473 and MNO-474.

Work at the Mono Basin sites was conducted by Archaeological Research Services, Inc., Virginia City, Nevada, under contract to the Oxbow Geothermal Company, Reno, Nevada, on order to evaluate the National Register-eligibility of these 2 and 21 other sites impacted by installation of a powerline between central Nevada and eastern California (Hall 1990). Hydration samples were processed by the author using facilities provided by R. E. Taylor, Archaeometry Laboratory, University of California, Riverside. V. L. Clay assisted in stratigraphic characterizations. M. E. Basgall and T. B. Snyder supplied the stressing but needed critical comment.

**Pavo Real: An Early Paleoindian Site in South-Central Texas**

*Jerry Henderson and Glenn T. Goode*

From June 1979 to January 1980, the Texas State Department of Highways and Public Transportation excavated the Pavo Real Site (41BX52), a stratified multicomponent site on the east bank of Leon Creek in northwest San Antonio, Bexar County, Texas (Henderson 1980). A discrete early Paleoindian component, isolated both above and below by alluvial gravel deposits, was discovered at the site. The Paleoindian deposit occurred 50 to 70 cm below the present-day ground surface in a paleosol averaging 15 to 20 cm in thickness. Contained
within this paleosol was a depositional lens having a thickness of ca. 3 to 5 cm. Clovis and Folsom artifacts were concentrated in a narrow band within this lens.

The lithic assemblage includes several major tool and debitage categories found at other early Paleoindian sites, such as Blackwater Draw (Hester et al. 1972), the Hanson Site (Frison and Bradley 1980), Lindenmeier (Wilmsen and Roberts 1978), and Shifting Sands (Amick et al. 1989). Recovered diagnostic artifacts include two reworked Clovis points, a small basal fragment of a third Clovis point, seven Folsom points including three small unfluted bifaces, and six Folsom preforms—some broken in manufacture.

A variety of scrapers constitutes the largest tool category in the assemblage. There are approximately 40 end scrapers, some with beaks and/or trimmed lateral edges; about half of this group are made on blades. Several side scrapers are made on flakes, and at least 10 to 12 flakes and blades have minor trimming and/or use modification of lateral and distal edges.

Among the debitage categories there are more than a dozen biface fragments, 8 to 10 cores, and the first core tablet flake found with an early Paleoindian component (D. Stanford, pers. comm. 1985). Included in the broken bifaces is a knife preform, 55 mm wide by 5 mm thick, and two possible blanks for Clovis points. The debitage sample is in the range of 15,000 specimens.

Paleoindian lithic technology at Pavo Real exploited an immediately available and abundant Edwards chert of variable quality. Some of this raw material was found on and near the site, and the large amount of debitage, including cores, cortex flakes, and shatter spall, indicates that the site was a quarry workshop as well as a campsite.

Preliminary analysis of the assemblage permits some observations about early Paleoindian lithic technology in south-central Texas. Aside from the fluting and pressure-flaking of Folsom (and possibly Clovis) points, lithic technology was based predominantly, but not exclusively, on hard-and-soft-hammer direct percussion. Clear evidence of this is seen in the platforms of many specimens in the tool and/or blade categories, as well as in core and flake debitage.

The direct percussion method is particularly evident among the platforms of 15 to 20 straight to moderately curved blades. However, because most of these blades are initial removals from cores, they are not representative of the total sample. Some initial blades have cortex, and a few have edge modification. Blade tools, on the other hand, are extensively modified. Although platforms have been removed from most blade tools, a few exhibit the marked curvature of some Blackwater Draw (Green 1963) and Kevin Davis (Young and Collins 1989) cached blades.

A bison (Bison sp.) tooth and three small unidentifiable bone fragments were the only faunal remains recovered. Two apparent hearth localities were present. Each was a small circular area, about 30 cm in diameter, consisting of burned soil, flecks of charcoal, and small pebbles. In apparent association with one of these hearths were three beaked scrapers and two large flakes with trimmed lateral edges.
Since the Paleoindian material assemblage at Pavo Real is a mixture from the encampments of both Clovis and Folsom people, efforts to separate the Folsom artifacts from the Clovis will be one of the more critical, and challenging, aspects of the analysis. Preliminary examinations by several archaeologists have yielded varying opinions concerning the cultural affiliation of the site’s blade industry. These fall into three groups: those who suggest a decided Clovis affiliation, those who suggest a primarily Folsom affiliation, and those who ascribe both Clovis and Folsom affinities to blade making.

Based on the number and variety of tools present, as well as patterning of features and artifact concentrations, it is believed that Pavo Real represents a multiple-activity, repeated seasonal encampment. Proximity to water and the availability of an abundant chert source were probably critical factors in selecting this location. The finding of a single bison tooth is not grounds for much speculation, but the campsite is located directly opposite a high limestone bluff that could have served as a bison jump. The bluff, along which Leon Creek flows today, forms the western wall of the narrow creek valley. It stands about 75 m west of the campsite.

The authors wish to thank Dennis Stanford, Robert J. Mallouf, and Michael B. Collins for technical advise and support.

Clovis Occupation in Oklahoma

Jack L. Hofman and Don G. Wyckoff

During the past two decades we have been collecting information on Paleoindian artifacts found throughout Oklahoma. In part as a result of this continuing survey, 90 Clovis points are now documented from Oklahoma. Although this survey has been opportunistic rather than systematic, and the documentation of Oklahoma Clovis material is in no sense complete, we believe that the present sample provides a useful source for beginning study of Clovis technology in the state. These data may serve as an initial basis for comparing and contrasting Clovis technology with other Paleoindian records in the region and with Clovis samples from elsewhere (e.g., Brown and Logan 1987; Copeland and Fiske 1988; Hester 1972; Huckell 1982; Meltzer 1987).

At present, information on the Clovis occupation in Oklahoma is limited to brief usually site-specific reports (e.g., Baker, 1957; Gettys 1984; Hammatt 1969; Thurmond 1990; White 1987) and to the well documented Domebo site finds (Leonhardy 1966). The only radiocarbon dates for Clovis in Oklahoma are from Domebo (Leonhardy 1966; Stafford et al. 1987). This paper is an initial step toward a broader and more integrated documentation of Oklahoma Clovis material.

Typological problems cannot be addressed here, but mention should be made of the difficulty in differentiating between heavily reworked Dalton and Clovis points and small basal fragments from central and eastern Oklahoma. Many Dalton points from the region are well fluted, but Clovis points are usually not beveled. This problem is further exacerbated by the extreme variability in basal form and degree of fluting which is exhibited by Clovis material having good contextual control (Frison and Todd 1986; Haury et al. 1959; Hester 1972; Leonhardy 1966). The problem with distinguishing between Clovis and Dalton in eastern Oklahoma and between Clovis and Plainview in western Oklahoma is unquestionably a factor limiting the number of documented Clovis points from Oklahoma. Problematic specimens are not included here.

Clovis points are documented from extreme western to eastern and northern to southern Oklahoma (Figure 1). This distribution is, however, uneven. Only three Clovis points are now recorded from the forested region of eastern Oklahoma while 38 are documented from the dissected prairie plains region and 30 from the western high plains region. The Cross Timbers or oak savanna

---

Jack L. Hofman and Don G. Wyckoff, University of Oklahoma, Oklahoma Archeological Survey, 1808 Newton Drive #116, Norman, OK 73019.
area of Oklahoma currently has 17 Clovis points with most from the Arkansas and Red River areas. The highest frequencies per county occur in Cimarron, Texas, and Caddo counties thanks largely to the close cooperation of avocational archaeologists residing there. The spotty nature of this initial Clovis distribution map indicates that there are undoubtedly many unrecorded finds. The current dirth of information on Clovis material from north central and central Oklahoma is perhaps the result of limited archaeological activity in the former area and the deeply buried late Pleistocene valley fills in the latter area. Only 21 of Oklahoma’s 77 counties have documented Clovis points.

The mean length of 57 specimens is 6.37 cm, mean maximum width (n=79) is 2.58 cm, mean basal width (n=68) is 2.29, and mean thickness (n=60) is 0.71 cm. the range in length is from 3.6 to 15.7 cm.

Figure 1. Frequency distribution of documented Clovis points in Oklahoma by county as of 1990.
Raw material utilization is in sharp contrast to that known for Oklahoma Folsom (Hofman 1987). The predominant material is Alibates (n=28; 31%), followed by Edwards chert (n=19; 21%), quartzites including Tecovas and Dakota (n=15; 16.6%), unidentified cherts (n=11; 12.2%), and a variety of materials represented by three or fewer specimens including crystal quartz, Florence, Boone, Johns Valley, Niobrara, and Oolagah cherts. Unidentified agate and chalcedony are also represented. One Clovis from Texas County appears to be made from Flattop Chalcedony (with its source in northeastern Colorado). Some interesting patterns are beginning to appear in the distribution of raw materials. Edwards chert is rare as Clovis points in the Panhandle region (n=2) where most pieces are made from Alibates and quartzites. Edwards chert Clovis points are primarily from southwestern and southcentral Oklahoma. The Florence, Oolagah, and Boone chert Clovis points occur in the general areas of their sources. The Niobrara jasper specimen is from Roger Mills County in westcentral Oklahoma.

Reported points are dominated by complete specimens (n=52; 57.7%), nearly complete pieces (n=13; 14.4%), and bases (n=20; 22.2%). Probable impact breaks are evident on 24 (n=26.6%) of the specimens and 9 of these were reworked after breakage. Lateral resharpening is also common. As samples for study increase it will be interesting to evaluate the possibility that impact breakage versus lateral resharpening may vary in different ecological regions. Much remains to be learned about Clovis in Oklahoma, but the initial summary provided here documents the potential this data set has in contributing to the general study of the Clovis occupation in North America.

Howard Gully: A Terminal Pleistocene Record from Southwestern Oklahoma

Jack L. Hofman, Lawrence C. Todd, Russell W. Graham, and Frances B. King

A stratified late Pleistocene site is yielding new paleontological, paleobotanical, stratigraphic, and archaeological evidence dating to about 11,000 yr B.P. Howard Gully (34GR121) is located on a tributary of the North Fork Red River near the western end of the Wichita Mountains in Greer County. Controlled excavation and exploratory trenching during 1989 provided a stratigraphic context for faunal and archaeological remains which had eroded from ponded colluvial deposits.

The initial discovery of a skull and postcranial elements of a fossil bison (Bison sp.) and other bones in the early 1970s sparked interest in the deposit. The bones were exposed in the base and side wall of a small gully which had formed in the spillway of a small pond. During construction, an estimated 2 to 4 m of Holocene fill was removed from the spillway area. The bison skull was crushed from pressure of overlying sediments and was not recovered except for some maxillary teeth. Other bison elements collected include an ulna, calcaneus, intermediate carpal, burned metapodial fragments, a third phalange, and unidentified bison-sized bone fragments. Some of these specimens show evidence of rodent gnawing which documents pre-burial surface exposure, or action by gophers. Weathering on most specimens is not severe. During the 1989 fieldwork, additional bison remains including mandible fragments, vertebrae, acetabulum, and a humerus were recovered in place. The MNI for bison is one.

The bison at Howard Gully is large with the size of the ulna (measurements UL3 and UL8 of Todd 1987) directly comparable (161 mm and 112 mm, respectively) to "males" from the Folsom-age Lipscomb bonebed (Todd et al. n.d.: figure 10). Other faunal remains, primarily collected during the 1970s, include a canid mandible, small mammal bones, and at least two genera of turtles including the extinct giant tortoise (Geochelone crassiscutata). All of the

Frances B. King, Archaeobotany Laboratory, CRMP, Bldg. 1, University of Pittsburgh Archaeological Research Center, 170 William Pitt Way, Pittsburgh, PA 15238.
surface remains were found eroding from the gully wall stratigraphically at or immediately above a radiocarbon dated level.

Two radiocarbon dates have been obtained for Howard Gully. The first is based on organic-rich sediments collected in 1987 from a cleaned profile at the head of Howard gully below the present gully floor (Hofman 1989). This sample is from the lower of two organically-rich lenses. An attempt was made to remove charcoal from the sediment and derive both a sediment and charcoal date for the deposit. Only a sediment AMS date was possible, however, and it is 11,060±220 yr B.P. (Beta-20359/ETH-2934). Because this date documented the relevance of the deposit to late Pleistocene studies in the area, further investigations were conducted in 1989. During the 1989 fieldwork, we again sampled the lower charred botanical layer at the head of Howard Gully and collected charcoal fragments from within 20 cm of the sediment date at the same stratigraphic level. This AMS date on charcoal was 10,810±110 yr B.P. (NZA-1461). These dates are in relatively good agreement, overlapping at one sigma between 10,840 and 10,920 yr B.P.

The dates provide a maximum age for the faunal remains from Howard Gully because the bones occur above the organic lenses, but in the same stratigraphic unit. This provides an important terminal age for *Geochelone crassiscutata* in this region. The *G. crassiscutata* material from Howard Gully has been compared directly to specimens of *G. wilsoni* and *G. crassiscutata*. The Howard Gully shell fragments compare well with *G. crassiscutata* and are much larger than *G. wilsoni*. A large portion of the plastron and carapace fragments are represented and the likelihood of redeposition is thought to be small.

Occurrences of *G. crassiscutata* have been summarized by Graham (1986), and terminal Pleistocene occurrences are extremely rare outside of Florida. Wisconsin records of *G. crassiscutata* are known from Florida, Mississippi, Texas, and now from Oklahoma. This species is also reported from Lubbock Lake, Texas (Johnson 1987), but its age there is uncertain. Fragments of *Geochelone cf. crassiscutata* are also documented from the Meriweather site (34CD304) in Caddo County, Oklahoma, but the age of that deposit has not been determined. The smaller *G. wilsoni* has been reported from the Clovis age Domebo site (Leonhardy 1966), also in Caddo County and from other Clovis sites on the Southern Plains (Moodie and Van Devender 1979).

Howard Gully provides an opportunity to study paleoecological and cultural processes at the end of the Pleistocene, a time of extinctions and of the appearance of the Clovis and Folsom cultural complexes. The occurrence of several delicate gravers and a Folsom point preform fragment from the eroded surface deposits at Howard Gully lend potential significance to the burned bone fragments which have been collected. The Folsom preform (Figure 1) represents a basal corner which was broken during manufacture and is made of Edwards chert. The Winters archaeological site, located 400 m upstream from Howard Gully, is a multicomponent campsite with a significant Folsom component (Hofman and Wyckoff 1987). Later archaeological materials are also documented from the vicinity, but these have been found on the eroded surface
of an ancient terrace at the Winters site, and on sandy Holocene deposits stratigraphically above the dated unit at Howard Gully.

The charred wood dated at Howard Gully has been identified as honey locust (*Gleditsia trianckanthos*). Although the western limit of honey locust is generally central Oklahoma (Fowells 1965), there are several small outliers in western Oklahoma and Texas which suggest that it may have been more common further west at some time in the past.

To date, fine screening of sediments produced few snails or micro-mammal remains. Study of flotation samples is not complete and analysis of pollen and phytoliths from the deposits is underway. Future work at Howard Gully will focus on recovery of additional paleoenvironmental information from stratigraphically controlled contexts. The variety of information to be gained through continued work at Howard Gully is of significance in comparing this locality in extreme southwestern Oklahoma with better documented terminal Pleistocene localities on the eastern Prairie margin (Ferring 1990; Leonhardy 1966) and on the High Plains to the west (Johnson 1987).

We appreciate the assistance and contributions of Lawrence and Gene LeVick who first brought this site to professional attention and who have supported our work there in many ways. Also, thanks to Roger LeVick, the Winters Family, Jerry Brooks, Brian Carter, Peggy Flynn, Walter Klippel, and Don Wyckoff for their contributions to this effort. Thanks to Ernest Lundelius and Rick Toomey for providing Geochelone specimens for comparison. The fieldwork was made possible through a grant from the University of Oklahoma Associates Research Fund and the inspired efforts of Anthony Dolan, Tamara Harper, Matthew Hill, Lorren Jackson, and Lara Prihodko.

The Miami Site Revisited: A Clovis Mammoth Kill in the Texas Panhandle

Vance T. Holliday, C. Vance Haynes, Jack Hofman, and David J. Meltzer

The Miami site (41RB1; also known as the Cowan Ranch site) is on the extreme northeast end of the Southern High Plains (Llano Estacado). It was discovered in 1933 and tested by local amateurs in 1934. Extensive excavations took place in 1937 under the direction of Glen L. Evans, working with E. H. Sellards and the Texas Memorial Museum (The University of Texas at Austin). The partial remains of five mammoth (Mammuthus columbi) (Sellards 1938; Saunders 1980)

were recovered along with three Clovis projectile points and a non-diagnostic stone tool. Miami was the third reported find of a Clovis mammoth kill, after Dent (Wormington 1957) and Blackwater Draw Locality 1 (the Clovis type site) (Cotter 1937). However, archaeologists did not fully recognize the Clovis type to be temporally or technologically distinct from other fluted points until after further research at the Clovis site by Sellards, Evans, and co-workers in 1949 and 1950 (Sellards 1952; Wormington 1957).

The site is on the flat, open surface of the Llano Estacado, but within 60 m of the heavily dissected terrain which marks the eastern margin of the Llano. When the site was first discovered there was no obvious topographic indication of the site; bone was simply being exposed due to plowing in a flat field. The excavations showed that the bone bed was in a small depression that filled with organic-rich silt (Sellards 1938, 1952). The bone bed was completely excavated and then the site was backfilled.

In July, 1990, the authors met to relocate the Miami site, determine its condition, and re-evaluate the stratigraphy and geomorphology in light of over 50 years additional geoarchaeological research on the High Plains. Upon our return we found the same situation that greeted Sellards and Evans: a flat field with no topographic indication of the site, but with numerous mammoth bone fragments at the surface. The site was relocated by first mapping the area of exposed bone in relation to a permanent datum set in the fence line southeast of the site. Fragments of bone and teeth plate enamel (n=336) were recovered over an area 60 m north-south by 40 m east-west. Most of the mammoth teeth fragments (35 of 49) are <2 cm maximum dimension. The largest piece of bone is 17 cm by 7 cm and weighs 439 g. During the collecting and mapping of bone fragments, two small bifacial thinning flakes of Alibates agate were found and mapped along the northeast margin of the bone concentration.

A trailer-mounted Giddings hydraulic soil-coring device was used to locate the filled depression. Seventeen cores were drilled in a t-shaped pattern through the area of the bone concentration. We essentially confirmed the stratigraphy reported by Sellards and can provide additional details on the soils and sediments. The bone bed was originally in a circular depression about 20 m diameter and a maximum 2.5 m deep. The depression is inset into a yellowish red (5YR 5/6, moist) silt loam with a well-expressed soil profile (Paleustoll); Sellards' (1938) "red sandy clay bedrock". The lithologic, stratigraphic, and pedologic characteristics of this unit are typical of the Blackwater Draw Formation, a layer of eolian sediment deposited episodically across the Llano Estacado throughout the Quaternary (Reeves 1976; Holliday 1989). Most of the sediment that filled the depression is a very dark gray (10YR 3/1, moist) silt loam referred to by Sellards as "dark [blue] sandy clay", "fine silt colored by organic matter", and "dark clays". A layer of dark grayish brown (10YR 4/2, moist) silt up to 10 cm thick, Sellards' "loess" zone, occurs 5-10 cm below the bone level and pinches out toward the margins of the depression. The bone level occurred 5-10 cm above the loess and was encased in another layer of black silt loam. Today the uppermost 30-40 cm of fill in the depression is backdirt from the excavation, a jumbled mixture of red and black silt loam. The
contact between the backdirt and the black silt loam marks the level of the bonebed.

The paleo-depression at Miami was almost certainly an ephemeral-lake basin or "playa", a very small scale version of thousands of such basins that dot the High Plains landscape (Walker 1978). This interpretation is based on the morphology of the depression and on the lithology of the basin fill. Though ubiquitous, the age and origin of these features is largely unknown, but long debated (e.g., Judson 1950; Reeves 1966; Osterkamp and Wood 1987). The presence of a Clovis occupation in the upper portion of the fill, however, shows that this basin was present for some time before 11,000 yr B.P. Several other Paleoindian sites are also reported from small playas elsewhere on the Llano Estacado (Roberts 1942; Johnson et al. 1987).

Samples for a variety of analyses were collected during the coring project. Sedimentological and pedological analyses are in progress. Soil samples for radiocarbon dating were collected from the bottom of the basin fill, from the fill just below the silt layer, and from just above the silt layer. The largest bone fragment is undergoing chemical analysis to determine its suitability for dating. These studies and additional field work will provide valuable data for understanding Clovis activities, and the evolution and paleoenvironmental significance of small playas and their fills. In particular, dating and further understanding of the "loess" layer is important because it may be a local manifestation of a Clovis period drought proposed by Haynes (1991).

We thank the following individuals for their assistance: George Arrington, Don Jenkins, Effie Jenkins, David, Diana, Erin, and Mitchell Locke, Ty Sabin, and Don Wyckoff. Support for this work was provided by grants to Vance T. Holliday from the National Science Foundation (EAR-8803761), to Jack Hofman from the University of Oklahoma Associates Research and Creative Activities Fund, and to David J. Meltzer from the National Geographic Society (3810-88).

Recent Excavations at the Munson Springs Site, a Paleoindian Base Camp in Central Ohio

Bradley T. Lepper and Jeffrey B. Gill

Continuing excavations at the Munson Springs site (Frolking and Lepper 1990) in the Raccoon Creek drainage of central Ohio have uncovered further evidence for a stratified series of prehistoric occupations beginning with, what may prove to be, a single episode of occupation by a small band of Paleoindian hunter-gatherers. During the summer of 1990, the Licking County Archaeology and Landmarks Society, working with the Ohio State University Department of Anthropology and the archaeological field school from Bloomsburg University,
LEPPER and GILL

Archaeology

excavated a series of test units at the site. Many of these units were placed away from the small mound (Locus A) tested previously (Frolking and Lepper 1990) in order to look for undisturbed deposits. Unfortunately, several of these outer units also evidenced considerable disruption of the deeper occupation levels as a result of the activities of subsequent site occupants. For example, in one unit a domestic pig (Sus) burial was encountered. However, in general, a remarkably consistent sequence of occupations was established which, to a limited extent, mirrors what was documented in the profile of the initial test trench (Frolking and Lepper 1990).

The upper 8 to 10 cm were a uniform medium brown silt loam. A light scatter of historic artifacts overlay, and to some extent, were mixed in with, a prehistoric component consisting of flint debitage, ceramics, and fire-cracked rock. A second stratum of light brown silt loam extended to between 14 and 20 cm below the surface. Small amounts of debitage and fire-cracked rock were concentrated in the uppermost portion of this stratum. These artifacts likely relate to an early Woodland occupation.

A third stratum, described as light yellow-brown silty clay loam, yielded a very light scatter of flint debitage and fire-cracked rock within the upper 2 to 3 cm of this stratum. The next 8 to 10 cm were virtually sterile. Between 28 and 30 cm below surface, a second light scatter of debitage and fire-cracked rock was observed in association with two possible postmolds or small pit features each 28 cm in diameter and respectively, 22 and 36 cm in depth. These two distinct deep components are of undetermined cultural affiliation. It is possible, however, that the deepest component corresponds to the Paleoindian occupation floor defined in previous, non-contiguous excavations. The overlying flint scatter may, therefore, relate to an early or later Archaic occupation. Further testing will be required to establish the precise number of components at the site and their chronological and cultural relationships.

Minute fragments of scattered hickory (Carya) charcoal, recovered in apparent association with the fluted preform reported previously, have yielded dates which are unrelated to the Paleoindian occupation. Two accelerator radiocarbon dates have been obtained for this charcoal. Beta Analytic reported a date of 2,445±60 yr B.P. (Beta-34437/ETH-6064) and the University of Arizona reported a virtually identical date of 2,445±65 yr B.P. (AA-5061). Therefore, this charcoal dates a single burning event associated with the construction of the early Woodland mound at Locus A. The early Archaic projectile points recovered from strata overlying this charcoal presumably are redeposited remnants of a formerly intact series of early Holocene occupations at the site.

The results of the test excavations conducted to date offer limited support for the interpretation of the Munson Springs Paleoindian component as a small winter base camp. It is located within a sheltered, south-facing hollow in close proximity to two natural springs. The two large diameter postmolds found in the lowest stratum beyond the mound area suggest that a substantial structure might have been present during the Paleoindian occupation. Such a structure could represent a relatively substantial, and therefore semi-permanent, winter
habitation for a small group, perhaps a nuclear or extended family. The predominant raw material represented in the Paleoindian tools and debitage is local Flint Ridge Flint and the debitage represents retouch from late stage bifaces.

The unfortunate, but not unexpected, absence of bone from the early levels of the site limits the potential for directly addressing questions of Paleoindian subsistence in this region. However, the indications of small group size, semi-permanent seasonal occupation, and small home range do not support notions of midwestern Paleoindians as highly mobile, specialized big-game hunters (e.g., Tankersley 1989).

The Archaeological Investigation of a Series of Early Paleoindian (Clovis) Sites in the Little River Region of Christian County, Kentucky

Edward E. Smith, Jr. and Andrea K. L. Freeman

Archaeological investigations at a series of four Clovis period Paleoindian sites in the Little River region of Christian County, Kentucky were conducted during the summer of 1990. The Little River is a tributary of the Cumberland River, and lies in the karstic portion of western Kentucky. The sites investigated comprise the Little River Paleoindian Site Complex, and include the Adams site (15Ch90), the Boyd (Ledford) site (15Ch236), the Ezell site (15Ch483), and the Roeder site (15Ch482) (Figure 1). Previous investigations of lithic material from these sites were conducted by Sanders (1983, 1988), and Tankersley (1987, 1989a, b, 1990). These sites were utilized at least in part for the procurement and reduction of Hopkinsville chert, a high quality cryptocrystalline lithic resource available locally in the Ste. Genevieve limestone. All of these sites have produced numerous diagnostic Paleoindian

Edward E. Smith, Jr., Glenn A. Black Laboratory of Archaeology, Indiana University, Bloomington, IN 47405.
Andrea K. L. Freeman, Department of Anthropology, University of Arizona, Tucson, AZ 85721.
artifacts, including fluted points and preforms. A blade technology figures prominently in the assemblages from these sites. The purpose of the research was to investigate the subsurface integrity of these sites and to assess their potential for addressing a variety of questions concerning Paleoindian lifeways in the region.

Much of the work focused on intensive, controlled surface collection and subsurface testing at the Ezell site (15Ch483). Preliminary analyses indicate that some activity patterning is discernible, despite intensive collection by local artifact collectors. Approximately nine sq m of the site was excavated. One limited area of the site produced subplowzone cultural deposits of an as yet unspecified nature, perhaps a filled natural depression. A series of stratigraphic profiles were obtained from the Boyd site (15Ch236) by means of

![Figure 1. Location of the Little River Paleoindian Site Complex.](image-url)
a hand auger. These cores suggest the presence of late Pleistocene deposits underlying Holocene alluvium. These deposits are located downslope from the Paleoindian component exposed on the surface.

Limited surface collecting and test excavations were also conducted at the Roeder site (15Ch482). One radiocarbon sample from the Ezell site and two from the Boyd site have been submitted for TAMS dating. Future research in the region will include stratigraphic testing for the purpose of reconstructing the fluvial history of the Little River, and locating sealed Paleoindian components.

Sediment samples were obtained from McGaughey Swamp to assess the potential for the preservation of pollen and other organic remains in order to address the paleoenvironmental history of the region. Unfortunately, there was no pollen preserved in the samples. A number of other locales for the extraction of sediment samples have been indentified, and additional palynological investigations are planned.

These investigations were conducted jointly by the Glenn A. Black Laboratory of Archaeology, Indiana University, and the Department of Anthropology, University of Arizona, and were sponsored by the Kentucky Heritage Council. The authors wish to thank C. Vance Haynes, Christopher S. Peebles, Thomas Sanders, and Kenneth B. Tankersley for their insight, and Mr. Carl Yahning for the use of his collections. The illustration was prepared by Rachel Freyman, GBL, IU.

Paleoenvironments and Delaware River Basin Stratigraphy

Michael Stewart

Archaeological and sedimentary stratigraphies from alluvial settings of the major river systems in Pennsylvania have been compiled under the auspices of the Bureau for Historic Preservation of the Pennsylvania Historical and Museum Commission (Vento et al. 1990). The work establishes a basis for relating sedimentary sequences to paleoenvironmental change, and identifies a number of recurring paleosols which are interpreted as the fingerprint of specific regional events. The framework employed is that of genetic stratigraphy, a concept derived from marine studies and elaborated upon by Vento and Rollins (1989) for use in terrestrial archaeological investigations in the Middle Atlantic Region of the Eastern United States. Each of the three river basin studies (Ohio, Susquehanna, and Delaware) provides a data set useful for inferring the nature of the environmental contexts in which prehistoric societies existed, a means of identifying chronostratigraphic units, and a predictive tool for designing excavation strategies in specific alluvial settings. The applicability of the Delaware River Basin portion of this endeavor (Stewart 1990) to the study of early Native American cultures is summarized below.

Four to five terraces representing Illinoian and Wisconsin glacial outwash, and Holocene alluvium characterize the middle and upper sections of the basin to heights up to 42 m above current stream levels. This generally corresponds with the scheme developed by Peltier (1949, 1959) and subsequently refined by Vento and Rollins (1989) for the Susquehanna River. Definition of the entire terrace system of the lower valley are not as straightforward due to the effects of sea level rise and tidal influence, although Illinoian and Wisconsin deposits have been mapped to some degree for this area (Peltier 1959). The bulk of post-15,000 yr B.P. alluvial sediments are found on landforms from 1.5 to 8.5 m above stream level. The most deeply stratified sequences occur on terraces from 4.5 to 8.5 m above stream levels and conform to what has been defined as Valley Heads terrace. Holocene sedimentary sequences representing potentially habitable landforms range from 2.4 to 4.8 m in thickness.

Pre-10,000 to 8,000 yr B.P. floodplains were such dynamic settings that preserved sediments and contexts pertaining to the Paleoindian and early Archaic periods in the basin are unlikely to be broadly distributed. The Delaware River had stabilized in its near-present channel sometime between

Michael Stewart, Department of Anthropology, Temple University, Philadelphia, PA 19122.
10,000 and 8,000 yr B.P. Stratified and relatively complete late Pleistocene through Holocene sedimentary sequences (and related archaeological deposits) are not a typical feature of remnant floodplains and terrace settings of the Delaware system. This parallels the evolution of the Susquehanna River system as described by Vento and Rollins (1989).

Somewhat complete sequences are known, however, with the Shawnee Minisink (McNett et al. 1985) and Upper Shawnee Island (Stewart et al. in press) sites being the best examples. The location of additional such localities can be predicted and their potential for furthering studies of Paleoindian and early Archaic cultures is inestimable. The problem remains that because of the transformation and destruction of many early contexts by natural processes, we may never be able to adequately gauge the full range of the initial prehistoric use of floodplain environments.

Underwater Excavations at Spring Lake: A Paleoindian Site in Hays County, Texas

Paul R. Takac

The San Marcos Springs emerge from the Balcones Fault escarpment near San Marcos, Texas. The springs were apparently utilized from Paleoindian to Late Prehistoric times. A dam constructed sometime before A.D. 1880 drowned the springs and adjacent land and created a small impoundment known as Spring Lake.

Underwater excavations of the modern lakebed began in 1978 at the Ice House site (41HY161), below the dam, under the direction of Joel Shiner (1979). Subsequent excavations at the Terrace locality (41HY147), within Spring Lake, were conducted intermittently from 1979 until Shiner's death in 1988. Although over 200 m\(^2\) were excavated and artifacts, debitage, and bone fragments totaling several hundred thousand specimens were recovered, only brief reports have been published (Shiner 1981, 1983). The author obtained possession of the notes and collections of this material in late 1989 in order to complete the analyses, conduct further excavations, and publish the results. Several dry-land localities around the lake have also been excavated (Garber et al. 1983; Garber and Orloff 1985; James Garber pers. comm. 1991).

Paleoindian projectile points recovered from the Terrace locality include three Clovis, one Folsom, and over 40 others including San Patrice, Dalton, Meserve, Golondrina, Plainview and Angostura. It should be noted that not all of the points previously identified as Paleoindian (Shiner 1983) are included here and that additional specimens may yet be located in the scattered collections. Preliminary analysis suggests that most of the points are made of local Edwards chert which outcrops along the Balcones Fault. Fragments of mammoth (*Mammuthus*), mastodon (*Mammut*) and bison (possibly *Bison antiquus*) teeth have also been found. The bone recovered exhibits a remarkable degree of fragmentation, probably due to various taphonomic processes. The virtual absence of non-enamel megafaunal elements makes it difficult to determine whether or not the Terrace locality is a kill-site. Species identification and MNI counts are not yet available but the assemblage appears to be representative of known Pleistocene and Holocene faunal communities in central Texas.

Nearly all of this material was recovered from either the lakebed surface or from disturbed deposits. Shiner reported that the deposits initially excavated were deflated and disturbed (1983, pers. notes), but that in a 50 m\(^2\) area further...
upstream and nearer the escarpment intact deposits, which approximate those reported 200 m to the east (Garber et al. 1983), were sampled. Examination of this exposed area supports Shiner’s assessment. The exposed strata appear well-bedded and undisturbed. At this time, however, the stratigraphy of the Terrace locality is unknown.

There are three objectives of the fieldwork now underway. First is the generation of a section map of the >2 m deep Terrace deposits. This presents significant difficulties due to the overlying water mass which typically collapses any vertical sediment exposure. To counteract this, a combination of planum or “cumulative section” (Barker 1986) and photomosaic techniques will be employed whereby excavations will proceed, step-wise, back down into the extant pit. A section drawing may then be constructed while recovering additional material with better provenience control.

The second objective is stabilizing the walls of the exposed excavation area and removing slumped deposits. Finally, an accurate map of the topography of the pre-inundation lakebed will be drafted in order to determine the relationship of the Terrace locality to nearby landsforms. The modern lakebed has an artificially level appearance due to a blanket of recent silt and organic debris. A plan map is currently being made utilizing a floating 1,600 m^2 grid and metal “sounding pole”. Preliminary results suggest that the Terrace locality is a relatively level area separating the escarpment and a former spring-fed channel. These results will be verified by randomly selected core samples.

Once these objectives are accomplished it will be possible to undertake further excavation in order to address the controversial interpretation of Spring Lake as an area where Paleoindian groups “maintained an almost sedentary hunting and gathering existence” (Shiner 1983:2) in close proximity to a large, stable spring and the flora and fauna it supported. It has been argued elsewhere (Takac 1990) that late Pleistocene/early Holocene central Texas may have been attractive to hunter-gatherer populations not only in terms of raw material availability (Johnson and Holliday 1984; Meltzer 1986; Shiner 1984) but environmental diversity as well (Bryant and Holloway 1985; Graham 1979, 1984). However, questions of Paleoindian settlement strategy and duration of occupation at Spring Lake must be addressed in the future with well provenienced archaeological data.

Partial funding for the research at Spring Lake is provided by a grant from the Institute for the Study of Earth and Man at Southern Methodist University. I would also like to thank M. Shiner, D. Ridlen, B. Lewallen, J. Tomassini, V. Fruit, J. Fruit, J. Harris, and D. Meltzer for their commitment and assistance. Finally, the cooperation of R. Dunn, A. White, D. Maples, and R. Mumme of the Aquarena Springs Corporation is greatly appreciated.

Bostrom: A Paleoindian Site in Southcentral Illinois

Kenneth B. Tankersley and Michael D. Wiant

The Bostrom site is a low density, multicomponent deposit located in St. Clair County, Illinois. It is situated on a 16.2 h ridge spur, which overlooks the confluence of Ogles and Silver creeks, tributaries of the Kaskaskia River. Paleoindian artifacts, fluted bifaces (projectile points, knives, and preforms) and unifacial tools, are scattered over the surface.

In July 1990, the authors learned that the site is threatened by subdivision expansion. Therefore, the Illinois State Museum, with volunteer assistance from the Illinois Association for the Advancement of Archaeology, began efforts to salvage the site’s Paleoindian components. These efforts include shovel testing, controlled surface surveys, and test excavations.

Initially, we excavated 170, 92-cm³ shovel tests along a east-to-west transect across one ridge crest. Shovel testing provided pedologic information, a coarse-grained vertical distribution of the cultural deposits, and an evaluation of site disturbance by recent tillage. The site was then plowed and a controlled pedestrian survey was conducted at five-meter intervals. Artifact locations were marked by pin flags, mapped, and identified by type and location. Three concentrations of Paleoindian artifacts were identified. The area containing the largest density of Paleoindian artifacts was selected for excavation. Preliminary excavations consisted of five 4 by 4 m units, subdivided into four 2 m squares.

These investigations have identified a large assemblage of Paleoindian tools (Figure 1). This assemblage includes 31 fluted bifaces (12 broken or exhausted fluted projectile points and 19 fluted point preforms), 4 channel flakes, and 174 unifacially retouched specimens (4 prismatic blades, 6 limaces, 3 gravers, 32 spurred end scrapers, 25 trianguloid end scrapers, 5 ovate end scrapers, 14 side scrapers, and 85 miscellaneous flake knives and scrapers). Typologically, the fluted bifaces fall into three distinct styles: Clovis, Gainey, and Holcombe-like points. All of the chipped stone tools are manufactured from non-local and exotic sources of lithic raw material including: Kaolin, Dongola, and Ste. Genevieve cherts (southcentral Illinois); Burlington chert (central Mississippi and lower Illinois valley); Attica chert (westcentral Indiana); and Knife River Flint (southwestern North Dakota).

The presence of three temporally distinct fluted point styles and a large assemblage of unifacial tools, all manufactured from non-local raw materials, suggests that Bostrom was an intermittently occupied habitation site between

ca. 11,200 to 10,200 yr B.P. (Haynes et al. 1984; Deller and Ellis 1988). The presence of broken and exhausted fluted points, broken fluted point preforms, and channel flakes suggests that the site was also used as a workshop. The typology of the fluted points, the assemblage of unifacial tools, and the quantity of non-local lithic materials are similar economic patterns found on Paleoindian sites located in northern latitudes (Ellis and Lothrop 1989; Tankersley and Isaac 1990).

This investigation was made possible through funds, equipment, and staff provided by the Illinois State Museum. Volunteer field and laboratory assistance was provided by the Illinois Association for the Advancement of Archaeology. The time and expertise provided by Larry Kinsella, Frances Knight, Marjorie Schroeder, Norman Rossen, Julie Morrow, and Jenny Tankersley were invaluable. We especially thank Pete and Rob Bostrom, who discovered the site in 1975.

Cody Complex Occupation in the Black Rock Desert, Nevada

Steve Wallmann and Daniel S. Amick

The potential for Paleoindian occupations to be found in the Black Rock Desert of northwestern Nevada was noted by Clewlow in 1968. Since that time, there have been few systematic archaeological studies of the area. However, numerous avocational archaeologists have actively surveyed the Black Rock Desert. Evidence provided by avocational archaeologists led to excavation of a partial bison (Bison) skeleton which was associated with a Scottsbluff point (Figure 1, SW-580). Dansie et al. (1988) described this find, known as the Wallmann Bison (26Hu58), which was radiocarbon dated at 5,240±230 yr B.P. (UCR-1436). However, the dated bone contained "little organic fraction." Poor preservation of this bone from the desert surface probably precludes a reliable radiocarbon date (i.e., Stafford et al. 1987).

Recently, the Desert Research Institute in cooperation with the Winnemucca District of the BLM initiated further studies of the Wallmann Bison locality. Interest developed through reports of a widespread scatter of "Square Based" points near this locality. Examination of private collections from this area has produced over 200 Paleoindian points so far (Figure 1). These Square Based points are morphologically and technologically identical to Scottsbluff, Eden, and other "Cody complex" artifacts (e.g., Frison and Todd 1987). Thurmond (1990) suggests a minimal estimate of 8,500-10,000 yr B.P. for the Cody complex.

Collections from this locality also contain numerous Great Basin Concave and Stemmed types. Pendleton (1979) has described both of these early point series from Nevada. Obsidian hydration evidence from the Komodo Site in the Central Sierras suggests a date of at least 9,000 years for Great Basin Concave
points (Basgall 1988). The Great Basin Stemmed Series may be slightly younger in age (Rusco and Davis 1987).

Despite the apparent variety in these associated artifact types, it is possible that some of them may be synchronous. Thurmond (1990) and Johnson (1989) have noted a pattern on contemporaneous diversity in late Paleoindian assemblages on the Southern Plains. While it is tempting to correlate stylistic diversity with ethnic diversity, its meaning remains enigmatic. Nevertheless, stylistic diversity is a convincing empirical pattern of the late Paleoindian archeological record of the Plains and may also be likely in the Black Rock Desert.

**Figure 1.** Cody complex projectile point/knives (PP/Ks) from the Black Rock Desert. Dashed lines indicate edge grinding. Identifications from left to right. Top row: private collection, SW-534, SW-584, SW-582; Second row: SW-581, private collection, SW-583; Third row: SW-555, SW-506, SW-556; Bottom row: SW-541, SW-545, SW-539, SW-580.
Johnson (1989) has discussed evidence for expansion of late Paleoindian groups from the Great Plains into the Eastern Woodlands of Texas and Oklahoma. It seems likely that similar expansion into the northwestern Great Basin may be represented by the Cody complex points of the Black Rock Desert. While the surface association of Cody artifacts with bison bones and early Great Basin point types is intriguing, the subsistence and settlement patterns of these groups and the timing and nature of their interaction with indigenous peoples remain to be determined. In any case, the presence of Cody complex groups about 800 km west of the Continental Divide may provide significant additional evidence for population movement out of the North American Great Plains during the late Paleoindian period.

This paper is dedicated to the late Jonathan O. Davis who recognized the significance of the Cody complex materials in the Black Rock Desert and supported the collaboration that resulted in this study.

Aleut Kayak-Hunter’s Hypertrophic Humerus

W.S. Laughlin, S.B. Laughlin, and S.B. Beman

The upper arm bones (humeri) of an Aleut (Unangan) man interred in an Aleutian mummy cave excavated in 1990, exemplify the hypertrophy of the humerus common to Aleut kayak hunters.

In Figure 1 the right humerus of the Aleut is compared with the right humerus of an 18th century Russian, a member of the Medvedev party massacred by Aleuts at Umnak Island, A.D. 1764. The Aleut is over 60 years of age, the Russian is closer to 35 years of age. The Russian was much taller (maximum femoral length 432 mm) than the Aleut (415) mm, and the humerus is accordingly longer: Russian 316 mm, Aleut 301 mm. The Aleut humerus however, is much more massive in its shaft dimensions, and in its large epicondylar breadth of the distal end of the humerus. In the Aleut all the areas for muscle attachments are larger and more rugose. The Deltoid tuberosity and the area for the Teres major, are exceptionally well developed. The bicipital groove is deeper in the Aleut humerus only at the superior end for the rugose areas for muscle insertions encroach onto the floor of the groove.

Hrdlicka prefaces his study of 172 male and 174 female Aleut humeri with the observation: “The bones of the arm in the Aleuts may well be anticipated to show some interesting conditions, for there were no people in the Far Northwest who, in the males at least, used the arms more intensively. They were fisherman and maritime hunters. This necessitated frequent and often protracted trips in their kayaks, involving a great deal of paddling, often of a strenuous nature, which was followed from late childhood to old age [Hrdlicka 1945:533].”

The first observation of this humeral hypertrophy in Aleuts is provided by Tarenetzky (1900), who illustrates the humeri of two Aleut males and includes the cross sectional areas.
Further studies of pre-Russian humeri, together with related elements, may designate the unique complex of muscle groups involved in double-blade single hatch kayak paddling, in which the paddler is seated and the pulling arm is alternately lower than the pushing arm.

Human Skeletal Remains Recovered from the Bonner Springs Locality, Northeastern Kansas

D. Gentry Steele, Joseph F. Powell, Larry D. Martin, and Wakefield Dort, Jr.

More than 50 human skeletal specimens have been recovered from channel bars along 19 km of the Kansas River near Bonner Springs, Kansas, and incorporated in the Kansas Museum of Natural History collections. A wide range of Pleistocene fauna, including mammoth (*Mammuthus*), mastodon (*Mammut americanum*), bison (*Bison antiquus* and *Bison bison*), woodland musk ox (*Symbos cavifrons*), and stagmoose (*Cervulces sp.*) have been recovered from the bars along with numerous Holocene faunal remains. The present report is based upon 58 human specimens curated or loaned to the Kansas Museum of Natural History (KMNH) in September, 1990.

While there are no reliable chronometric dates for the assemblage, human remains from this locality are thought to be late Pleistocene or early to mid-Holocene in age, based on the stratigraphy and antiquity of nearby deposits. Near the locality of the channel bars at Bonner Springs, Pleistocene gravels are overlain by sediments of the Newman terrace fill, a lithostratigraphic unit dated 10,430±130 yr B.P. (Beta-2931) to 8,940±90 yr B.P. (DIC-3210) (Johnson 1987; Johnson and Logan 1990). ESR (electron spin resonance) data indicate that some of the human remains can be differentiated from the recent Holocene fauna recovered from the bars, and appear more similar in antiquity to the late Pleistocene or earlier Holocene remains.

The 58 human skeletal elements from the locality are represented predominantly by large, durable bones: 19 femora, 12 parietals, 10 frontals, 5 mandible fragments, 4 occipitals, 3 humeri, 2 temporals, and 2 tibiae. One intact subadult calvarium was also present in the sample. Preliminarily, each human element was assigned to one of three grades of fossilization based upon degree of staining and mineralization. Grade 1 specimens (n=22) appeared to be uniformly mineralized with darkly stained cortical bone, dark brown to black in color. Staining and mineralization in Grade 1 human bone resembled that noted in...
some of the Pleistocene and early Holocene fauna but was not seen in late Holocene fauna. Grade 2 elements (n=33) appeared less mineralized and the stain on the cortical bone was restricted to the external surface while the interior bone remained a lighter shade of brown or tan in color. Grade 3 specimens (n=3) were not mineralized and were a light brown color to chalky white color, the exterior and interior cortical bone being more equally stained. The state of preservation in Grade 3 specimens is similar to middle or late Holocene human remains from the Great Plains. There was no association between the grade of mineralization and a particular point bar.

Eleven Grade 1 specimens exhibited minor to extensive water and grit abrasion. Minimal water abrasion was noted in one Grade 2 specimen. Two explanations can account for the taphonomic difference between grades. Water damage and bone mineralization may be a function of time, with older specimens accumulating more damage and chemical alteration. Alternatively, the damage and mineralization in Grade 1 elements may be due to a longer period of direct exposure to water rather than because of their greater antiquity. The presence of only large, heavy skeletal elements with minimal wear and the sharp angularity of gravel clasts at the Bonner Springs locality, suggests that high velocity, short distance transport of gravel and bone took place (Johnson and Logan 1990; Johnson 1987; Holien 1982).

The MNI of humans represented by the complete sample was 11, based on the number of frontal bones. If the grades of mineralization and staining represent human remains of different antiquity, an MNI of 14 is indicated: four Grade 1 individuals (three adult frontals and one subadult humerus), eight Grade 2 individuals (seven adult left femora and one subadult calvarium), and two Grade 3 individuals (two adult left femora). Since we can not confirm the grades represent relative differences in antiquity, the most conservative MNI is 11.

Of those 11 frontals for which age could be determined two were early adolescent (12 - 15 years) (KMNH 54011 and 87790), two younger adults (20 - 30 years) (KMNH 94002 and 54038), five adults (20 - 50 years) (KMNH 87716, 87728, 97032, 54039, 87869), and one old adult (50 plus years) (no catalogue number). Accurate estimates of sex were impossible for most elements, but marked differences in size and robusticity of some elements indicated that both sexes were present.

Indications of the physical appearance of individuals from the locality were limited. The intact Grade 2 calvarium (KMNH 88790), a late child or early adolescent, is dolichocranic (long-headed). Five frontals (KMNH 54088, 87716, 87869, 94002 and one uncataloged), all Grade 2 preservation, exhibit low rising foreheads suggesting these individuals would have been characterized by low as well as long heads. These five frontals also exhibit marked flattening due to some form of cultural modification. It appeared that the flattening did not resemble frontal flattening seen in some Late Prehistoric agriculturalists, but rather a type of deformation caused by the use of a tumpline or similar devise for carrying loads.

One Grade 1 femur (KMNH 103409), was 459 mm in length, suggesting the individual was 170±3.4 cm tall assuming the robust femur represents a male
(based upon Genoves' (1967) corrected formulae; Bass 1987). The mean platymeric index (index of flatness) for 14 Grade 1 and Grade 2 femora was 80.7, indicating extreme lower body musculature for these individuals. A well developed gluteal tuberosity was present in seven femora with extreme flattening.

Several medical disorders were present. Periostitis was documented for one Grade 1 mandible (KMNH 103634), but no caries were documented in the assemblage. Evidence of an evulsed internal pterygoid muscle was present on one Grade 1 mandible (KMNH 103605). A projectile point was found embedded in the ventral side of one Grade 1 femoral neck (KMNH 103409). Unhealed hairline fractures radiating from this wound were also visible.

Postmortem cultural modification, indicated by fine cut marks were noted on the posterior aspect of one Grade 2 proximal left femur (KMNH 87726) between the lesser trochanter and femur head. The cut marks on this specimen are similar to those associated with the dismemberment of the body for secondary burial.

In summary, the Bonner Springs human bone assemblage, or a portion thereof, represents potentially one of the earliest and largest late Pleistocene/early-mid Holocene human assemblages recovered from the Central Plains, and provides us with a unique view of early North American populations in this region.

That Clovis-like, basally-thinned or fluted projectile points exist in the Mojave Desert is well known, but the sporadic occurrence of such implements has hindered attempts to clarify their temporal and cultural parameters. This also underlies a long debate over relationships between fluted and late Pleistocene/early Holocene stemmed points (cf. Willig, et al. 1988), variously labelled Lake Mohave, Silver Lake, Great Basin or Western Stemmed, and the like. Part of the problem is that nearly all fluted points in the region are surface finds, another the lack of precise provenience and compositional detail on the other kinds of cultural materials (if any) present at fluted point locations visited by early researchers. Work during the past decade at Fort Irwin, a 2,650 km² military installation in the Mojave Desert, has enlarged considerably the sample of fluted and stemmed points from well-documented contexts. Investigations in the last two years almost doubled the fluted point count and recovered many additional stemmed forms, bringing current totals of each to 17 and 259 specimens, respectively (Basgall 1991; Basgall and Hall n.d.; Hall n.d.; Jones 1991). Offered below are observations on the fluted-stemmed question in light of the Ft. Irwin distributional data.

The eight recently acquired fluted points derive from Nelson Basin in the northwestern portion of the fort; all conform to the definitional criteria of Warren and Phagan (1988), and are morphologically similar to fluted variants elsewhere in the Great Basin. One was an isolated find, the other seven come from two large sites (SBR-2355, SBR-2356) containing abundant, diverse assemblages of artifactual debris including numerous stemmed points, characteristics common to many of the Mojave Desert locations where fluted points have been encountered. Mean hydration values of 14.7 (n=18, sd = 1.5) and...
13.0 (n = 16, sd = 1.7) microns on artifacts of Coso obsidian from the Nelson Basin sites, when compared to regional hydration profiles for this glass type, attest strongly to the substantial antiquity of the two localities. Historically, there are three fundamental scenarios on fluted-stemmed point relationships in western North America: (1) these point forms are of different ages; (2) they are essentially comparable in age but have entirely separate cultural origins; and (3) they both belonged to the same, broader adaptive system known by such appellations as the Lake Mohave Complex or Western Pluvial Lakes Tradition. Despite years of effort, though, clear resolution of these alternative reconstructions continues to be evasive. Benefits of examining the Ft. Irwin distributions are the facts that large tracts of the post have been surveyed intensively and excavations, often extensive, have been conducted at many of the identified locations. Patterns at Ft. Irwin, therefore, are almost certainly representative of that area and probably applicable to the general desert region.

Including the Nelson Basin examples, isolated finds originally accounted for three of the 17 Ft. Irwin fluted points, 14 occurred at seven sites. One site, however, comprises an immense (0.8 by 2.6 km), discontinuous scatter of prehistoric stone quarrying debris along a series of washes. Since the two fluted specimens found here fell outside main quarry loci, it seems more appropriate to consider both as isolated finds. The other six fluted point sites feature significant accumulations of residential remains and all produced stemmed points, usually in large numbers. Five (29.4%) of the fluted points, hence, can be classified as "isolates", 12 (70.6%) as deriving from "site" contexts. Contrariwise, only four (1.5%) of the stemmed points from the fort constitute isolated finds, 33 sites having yielded 255 (98.5%) of the total 259 specimens. At Ft. Irwin, then, fluted points alone have not been found at any sites and, where associated spatially with occupational debris, always co-occur with stemmed forms; meanwhile, 82% of the sites (33) that have yielded either point form produced only the stemmed variety. Viewed another way, isolates make up 46% of the fluted point as opposed to 11% of the stemmed point locations. Equally marked is the contrast in mean specimen counts per location: 1.5 for fluted vs 7.0 for stemmed. It seems apparent that distinctly different processes where responsible for the deposition of these point forms.

This is further encouraged by variability in the types of stone used to manufacture such artifacts (cf. Warren and Phagan 1988). For example, three fourths of the fluted points (76.4%) are cryptocrystalline, the others being felsite (11.8%), obsidian (5.9%), or quartz (5.9%). Conversely, just a fourth of the stemmed points (26.1%) are cryptocrystalline, while well over half are basalt (43.6%), rhyolite (10.9%), or felsite (8.2%); accounting for the remainder are obsidian (10.9%) and quartz (0.4%) pieces.

The divergent depositional and material profiles outlined have two likely behavioral explanations, emerging either through the actions of independent cultural systems, or as a consequence of extreme functional differentiation within a single technological complex. In the first instance, the sometime spatial convergence of fluted and stemmed points is fortuitous, reflecting
multiple occupations of a location. With regard to the second possibility, it may be that the greater dispersion of fluted points and their propensity to occur as isolates relates to a specialized role in off-site hunting, while the tendency for stemmed artifacts to occur strictly in residential contexts may imply a more generalized processing orientation (serving as projectile points, but also for a host of cutting/scraping tasks). This would indicate that the conventional emphasis on stemmed points as hunting weapons is far too restrictive, and could also account for the large numbers of such artifacts at many locations.

Although not conclusive, variation in the overall disposition of fluted and stemmed points in the Mojave Desert is striking enough to suggest associations with different cultural systems, which would, in turn, explain the occasional reports of discrete fluted point accumulations in adjacent parts of the Great Basin (cf. Basgall 1988; Campbell 1949; Pendleton 1979). The alternative seems to dictate a much higher incidence of co-occurrence than seen presently, unless the degree of artifact specialization was truly remarkable. Whether a typical weapon form used to penetrate game or a specific kind of cutting tool, fluted points should be found more frequently with other components of the Lake Mohave tool-kit. Even if, as appears plausible, fluted and stemmed points were produced by entirely different systems, this does not endorse the traditional view of stemmed bifaces exclusively as projectile points. Any of several factors militate against such a characterization: the tremendous morphological variability evident in extant stemmed point assemblages; their superabundance at many of the sites where they occur (a 7.7 average per site exceeding that for any other point series at the fort); and, more indirectly, emerging faunal data that downplay the importance of large game in early Holocene subsistence patterns across Ft. Irwin. With the continued accumulation of specimens from protected, buried contexts, more refined use-wear studies and greater morphological controls will quite probably lead to recognition of significant functional variation among stemmed points in the Mojave Desert.

Rhyolite Sources in the Carolina Slate Belt, Central North Carolina

I. Randolph Daniel, Jr., and J. Robert Butler;

North Carolina archaeologists have long noted that a primary material used to make stone tools was a very fine-grained metamorphosed volcanic rock called rhyolite from the Carolina Slate Belt in the Eastern Piedmont (North Carolina Geological Survey 1985). Geologically, this rhyolite has a restricted distribution, occurring in a broken band of outcrops in and around the Uwharrie Mountains located in the central portion of the Carolina Slate Belt. Recently, with support from the National Science Foundation (BNS-892164), we have attempted to locate the sources of this stone and to identify its geological variability.

Ultimately, the results of this work will be used to identify the rhyolite types present in a previously unanalyzed portion of the Hardaway site assemblage. The Hardaway site (Coe 1964) is located within the Uwharrie Mountains along the western bank of the Yadkin river in an area of abundant metavolcanic stone. Additionally, raw material variability will be examined from several hundred lanceolate and notched points as part of a wider survey of artifact collections. This projectile point survey will address the geographic...

A preliminary sorting of the stone types present in the Hardaway-Dalton, Palmer, and Kirk components from the Hardaway site suggests that the vast majority of the combined assemblages is composed of rhyolite. It is predominantly a dark gray aphanitic rhyolite, mostly massive and aphyric, but in some cases with scattered phenocrysts and/or flow banding. The remaining minority types include 1) white to clear vein quartz; 2) light green, laminated metasiltstone, commonly called “argillite”; and 3) light to dark grayish-green, extremely fine-grained stone, somewhat chert-like in appearance, and tentatively identified as a metasiltstone. Isolated examples of jasper and various cherts are also present, more so in the debitage than in finished tools. Although jasper may have been obtained from the Piedmont, the chert’s sources probably lie in the Ridge and Valley Province to the west, and in the Allendale quarries of the Coastal Plain to the south.

Initial fieldwork was conducted during the winter and spring of 1990 using previous geological (e.g., Conley 1962; Dover 1985) and archaeological (e.g., Cooper and Hanchette 1977; Cooper and Norville 1978; Hargrove 1989; Harmon and Snedeker 1988) work to identify rhyolite quarries or potential rhyolite sources in the vicinity of the Uwharrie Mountains. A total of 11 quarry sites, some of which exhibited spectacular evidence of use, were located and/or revisited and sampled for petrologic analysis.

Based on the results of macroscopic and thin-section analysis, the rhyolite unit mapped by Conley (1962) can be subdivided into distinct types based on color, nature and abundance (or absence) of phenocrysts, grain size, presence of flow banding, and presence of special features such as spherulites. However, we have found that the most consistent and useful basis for subdividing rhyolite types used prehistorically are the nature and percentages of phenocrysts. Accordingly, four subtypes have been identified including 1) aphyric; 2) plagioclase porphyritic; 3) quartz porphyritic; and 4) plagioclase-quartz porphyritic. Our future research will determine if the chemical composition of rhyolites can be used for further detailed characterization and to help in identifying sources.

Our field data and thin-section analyses indicate that the dominant source of the dark-gray, flow-banded, aphyric rhyolite that is so abundant at the Hardaway site is probably from Morrow Mountain. Morrow Mountain also happens to be the most intensively quarried source yet located. We cannot, of course, rule out the possibility that this rhyolite was obtained from quarries outside the surveyed area—this possibility is currently being evaluated by additional fieldwork. However, given that Morrow Mountain is only 8 km south of Hardaway, we feel that is is the most likely candidate.

The sources of the less abundant dark-gray, porphyritic rhyolites in the Hardaway assemblage occur in areas just north of Morrow Mountain and across the Yadkin River to the east of Hardaway. We have found several quarries of these porphyritic rhyolite types located just a few kilometers from the Hardaway sources of the specimens in the Hardaway collection.
The Uwharrie Mountain range was a region of extensive prehistoric quarry use. Virtually every rhyolite-capped mountain appears to have had it stone exploited to some degree during the past. We tentatively conclude that the vast majority of the stone present in the Hardaway assemblage was obtained from quarries not more than 10 km from the site. Most stone probably came from Morrow Mountain, just south of the site and on the same side of the river. The apparently less desirable various porphyritic rhyolites could be obtained even closer, at several sites 4 or 5 km from Hardaway, on both sides of the river.

The Evant Cores: Polyhedral Blade Cores from North-Central Texas

Glenn T. Goode and Robert J. Mallouf

The discovery of three polyhedral blade cores with probable Paleoindian affinities was brought to the attention of archaeologists in 1990. The find was traced to a plowed and deflated field on the crest of a narrow ridgeline of Cretaceous limestone in Hamilton County, Texas. The cores were found by a landowner among one of numerous residual deposits of Edwards chert that occur across the crest of the ridge. Although uncertainties still exist as to the precise location and date of the discovery, several lines of evidence suggest that the cores were once part of a stone cache that was disturbed and dispersed by plowing.

The three polyhedral cores (Figure 1) are fashioned from two slightly different varieties of locally available, high quality Edwards chert. Two of the cores are heavily patinated, while the third exhibits a spotty to complete patina. Minor plow damage to two specimens reveal interior stone color ranges of light gray to light bluish-gray chert. All three cores are roughly cylindrical with pointed distal ends.

One specimen (Figure 1, A) is a prepared but little-used core nucleus. This core still retains patches of cortex on opposing faces, and it exhibits only one blade scar. Its sub-round platform was prepared by the removal of three successive flakes, followed by trimming of the face and edge. Maximum dimensions: length - 134 mm; platform diameter - 76 mm; core circumference - 235 mm; weight - 792 g.

The second specimen (Figure 1, B) is a near-depleted, final stage polyhedral nucleus. It is the by-product of skillful, large blade production. The final blade removal attempt was unsuccessful, however, and subsequent platform rejuvenation resulted in an imperfect, rectangular-shaped platform surface. One long blade scar on this specimen originates from the opposing, or distal, end of the core. Maximum dimensions: length - 161 mm; platform - 65 by 29 mm; core circumference - 210 mm; weight - 893 g.

The third core (Figure 1, C) is similar to the second in that it represents a very sophisticated level of blade production. The removed blades were smaller,
finer, and thinner overall—probably demanding a great degree of precision. The rejuvenated platform is circular. Maximum dimensions: length - 147 mm; platform diameter - 55 mm; core circumference - 180 mm; weight 586 g.

All three cores were originally much larger, as attested by an absence of proximal, and scarcity of distal, blade scars. During the process of blade production, damaged or deficient core platforms were repeatedly rejuvenated through the removal of two or three flakes (similar to core tablet flakes) struck from the platform edge, and followed by a series of smaller removals. Platform rejuvenation appears to have been accomplished with direct percussion, and with the intent to create concave, or dished, platform surfaces with slightly protruding, rim-like platform edges. While precluding the use of certain direct percussion techniques, the combination of the rim and adjoining dished platform surface provided an ideal seating for a punch in removing blades through indirect percussion. In addition, this combination of platform features ensured a $75^\circ - 85^\circ$ platform edge angle, which seems to be critical for efficient indirect percussion blade manufacture. The final reshaped and virtually unused platforms or the Evant cores are good evidence that they were cached for future reuse.

Further clues to Paleoindian blade production are seen in shared traits among the three cores. For example, contouring of the core face was critical for the consistent production of straight, parallel-sided blades. Segments of irregular or too prominent arrises on core faces were sometimes straightened and/or lowered through the removal of clustered small flakes originating from-and perpendicular to-the arrises. In order to complete arris preparation, an oblique removal was then struck from the distal (pointed) end of the core in such a manner as to intersect and undercut the lower party of the problematical arris, thus facilitating proper blade termination (feather or shallow hinge). The blade was then struck off the core at the intersection of the arris with the prepared platform. All three cores exhibit failed blade attempts above arrises prepared in this manner.

Lacking corroborative evidence, the cultural affiliation of the Evant cores cannot be demonstrated irrefutably. However, a comparison with Old and New World blade technologies (e.g., Barnes 1947; Bordaz 1970; Bordes 1968; Green 1963; Hester et al. 1972; Hammatt 1970; Sanger 1968) leaves little doubt that these cores belong to one of the earliest New World cultures, probably Clovis. Methods of core preparation and reduction techniques revealed among the Evant cores are strikingly similar to those of the Old World Paleolithic.

The extreme blade curvature found among cached Clovis blades from the Blackwater Draw (Green 1963) and Keven Davis (Young and Collins 1989) sites is not evident among blade scars of the Evant core assemblage. However, further reduction, which seems to have been intended, could have produced similarly curved blades from at least two of the cores (Figure 1, A and B). The Evant cores were in this case used to produce long, flat-to-moderately curved prismatic blades more like those typically found among utilitarian Clovis assemblages from Blackwater Draw, Pavo Real (41BX52; Henderson 1980) and other Clovis sites—a further testament to the technological flexibility of Clovis knappers.
The authors wish to thank Mr. Lloyd Ford for allowing examination of sites on his property, and Bill Metcalf, J.B. Sollberger, Michael B. Collins and David J. Meltzer for their assistance in obtaining the specimens for study, and for technical comments. Pen-and-ink drawings are by Ms. Sharon Roos of Austin, Texas.

The Clarks Flat Site Lithic Analysis

Michael F. Rondeau

The Clarks Flat site is located on the western slope of the Central Sierra Nevada mountains of California. This site, CA-Cal-S342, is one of a number found on Clarks Flat, a relict meander proving a relatively flat terrain of 13 ha in the generally narrow, steep-walled Stanislaus River Canyon at an elevation of 350 m (amsl).

Excavations in 1985 found cultural deposits to a depth of 2.5 m. Four cultural strata were identified. From top to bottom, Stratum I was radiocarbon dated to be more recent than 2,200 yr B.P., Stratum II was radiocarbon dated between 6,750 and 6,250 yr B.P., Stratum III radiocarbon dated between 9,600 and 8,600 yr B.P., and Stratum IV which yielded a radiocarbon date of 11,720±145 yr B.P. (Beta-14299) (Peak and Crew 1990).

Michael F. Rondeau, Rondeau Archaeological, 10 Alvares Ct., Sacramento, CA 95833
None of the radiocarbon samples were found in direct association with cultural features. The upper portion of Stratum II yielded a series of wide stemmed points named Stanislaus Broad Stemmed which have remarkable similarities to Pinto Series points found elsewhere in the far West. Strata II, III, and IV yielded a variety of Western Stem Series points. Stratum IV, however yielded only limited quantities of flaked stone. Ground stone and a small number of soapstone artifacts were also recovered from Stratum II.

The lithic analysis encompassed 16,402 flaked stone artifacts from the lower three strata (Rondeau and Rondeau 1990). This included the study of 15,322 pieces of debitage, 581 artifacts representing biface manufacturing and use (including 320 classifiable projectile points), 189 whole and fragmentary unifaces, 105 cores, 102 hammerstones, and 12 pointed drill-like specimens.

The biface study indicated that a complete reduction sequence of percussion and pressure biface manufacture was pursued at the site as was the replacement on shafts of broken projectile points. This replacement was suggested by the fact that more than 40% of the point fragments were basal elements. This data, along with numerous point tips exhibiting evidence of rejuvenation, suggests that a substantial number of the recovered specimens came to the site in use damaged form.

The evidence suggests that most of the obsidian arrived at the site in the form of finished or nearly finished bifaces. Of 4,242 specimens, 87.3% of the obsidian debitage was less than one centimeter in maximum dimension while showing technological attributes that result from final shaping and rejuvenation of such pieces. Of the 31 obsidian bifaces, 30 clearly indicated finished pieces. The obsidian hydration analysis (Jackson 1990) suggests that most of the obsidian is no older than the temporal placement of Stratum II.

Although over 79% of the cores had a unidirectional pattern of flake removals, percussion blade production was not indicated by these specimens or by the debitage. This pattern of core reduction, to the exclusion of most other forms (a few multidirectional and undiagnostic fragments complete the core collection) has not been recognized elsewhere in the Sierra Nevada. This finding may suggest a potential temporal maker for earlier assemblages in the region.

For the unifaces (189), 55.5% were found to retain use wear. Numerous specimens appear to have been heavily rejuvenated and some appear to have been broken during rejuvenation attempts. The debitage study identified 26 uniface retouch flakes, 4 of which clearly retained use wear.

A total of 123 used specimens (not including the battered hammerstones) were identified by a strict criteria of use rounding, excluding various forms micro-flaking and weathering rounding. These artifacts included 52 unifaces, 49 uniface fragments, 33 edge modified flakes, 6 pointed tools, 4 large percussion shaped unifaces, the 4 uniface, 3 cores, and 2 bifaces. A variety of uses for the hammerstones may be suggested by their varied forms which may included percussion flaking of stone, ground stone shaping, abrading, a pulping or mashing, and perhaps some sort of heavier bashing activity.
The Clarks Flat site has provided the first strong documentation for early Holocene occupation in the region. It has also provided the first archaeologically collected date hinting at human presence in California prior to 11,000 yr B.P.

The Early History and Archaeology of Nebraska Paleoindian Sites

David J. Meltzer

It has recently been suggested in this journal that a series of “virtually identical discoveries (by paleontologists) of extinct bison in association with projectile points were largely ignored by the archaeological establishment in the early part of the twentieth century” (Rogers and Martin 1986: 43-44), and that the Folsom discovery in 1927 was “neither unique nor decisive in changing perceptions about the existence of Paleoindians,” which thus remained controversial until the advent of radiocarbon dating (Rogers and Martin 1987:82). Three Nebraska Paleoindian sites are central to these claims, and so it is appropriate to examine briefly the circumstances surrounding the discovery of those sites, and the reaction (if any) of archaeologists (for a fuller discussion of these and the other sites on which these claims are based, see Meltzer 1991).

The Custer County site is identified as one of the “remarkable...scientific discoveries,” made by paleontologists which had “little effect... on the archaeologist of that time” (Rogers and Martin 1986:44). In truth, the discovery had no discernible effect on the paleontologists who excavated it. In July 1929, Erwin Barbour, paleontologist and Director of the Nebraska State Museum had C. Bertrand Schultz excavating Pleistocene marls in the South Loop Valley, Custer County.

Schultz later reported that “after an hour of digging to determine whether or not the new find (a bison) was worth collecting, the writer found an artifact (specimen 2-16-7-29), in association with a portion of bison rib” (Schultz 1932:271). The artifact was important “because of its association with the fossil bone, and because it differed greatly from the common arrow-heads of the Plains indians!” (Schultz 1932:271).

Yet Schultz wrote those words two years after the fact. When the artifact was actually found in 1929 it was not accorded any significance: in a detailed

David J. Meltzer, Department of Anthropology, Southern Methodist University, Dallas, TX 75275
letter to Barbour, reporting on the day's finds, Schultz made no mention of the point—only a "most beautiful" newly found bison skull (Schultz to Barbour, July 16, 1929, Barbour Papers, Nebraska State Museum, hereafter EHB/NSM). Barbour responded with congratulations on the new skull, but no word of the artifact then or in any subsequent correspondence that field season (Barbour to Schultz, July 18, 1929 EHB/NSM).

In fact, Barbour and Schultz paid attention to the Custer County artifact only after archaeologist W.D. Strong, then at the University of Nebraska, learned of its existence in 1930 and, in Schultz's words, "urged further investigation and excavation" (Schultz 1932:272). In September of 1930 Strong accompanied Schultz to the site to help map it and estimate its age (apparently late Pleistocene - Schultz 1932:272).

Perhaps owing to Strong's emphasis on the archaeology, greater attention was paid to artifacts found the following summer at the Meserve site. Bison had been excavated by zoologist F.G. Meserve from the site in 1923. There is no evidence that at the time Meserve recognized the bison as an extinct species, or appreciated the significance of the associated projectile point. The Meserve site originally attracted Barbour's attention as a source for bison bone for museum display (Barbour to Meserve, June 4, 1931, EHB/NSM). The initial correspondence between Barbour and Meserve in the summer of 1931 makes no mention of artifacts.

Barbour sent Schultz to excavate at the Meserve site in the summer of 1931 to recover more bison bone. On July 25, 1931, the crew also found a projectile point, and subsequently learned this was the second to come from the bone bed (Barbour and Schultz 1932a). Meserve had found one in 1923, but only after prompting by Barbour in late 1931 learned of its significance (Barbour to Meserve, November 12, 1931, EHB/NSM). Schultz by then appreciated the importance of the artifacts (Schultz to Barbour, late July, 1931, EHB/NSM). All the same, Barbour, who had just spoken with Strong of the find, felt obliged to remind Schultz that "The arrow points are very important. I hope you have saved them and not sold them" (Barbour to Schultz, August 13, 1931, EHB/NSM).

More artifacts would be found with fossil bison at the Scottsbluff site the following summer (1932). It has been reported that when the artifacts were discovered, Loren Eiseley "begged to be sent elsewhere, out of fear of what involvement with Paleoindian site would do to his career as an anthropologist" (Schultz 1983:32). In fact, Rogers and Martin (1986:44, 1987:81) use this colorful vignette as prime evidence that even after the Folsom find Paleoindian sites remained controversial. But, unfortunately, the vignette is untrue.

The Scottsbluff site when discovered was thought to be only a paleontological quarry, and was being worked for bison bone (Barbour and Schultz 1932b). For the first month or so of the 1932 season, no artifacts had been encountered, or where even expected. Eiseley, then on the Scottsbluff field crew, wrote Barbour to say he had received an offer to do archaeological field work in the Southwest, and wished to take it (Eiseley to Barbour, July 16, 1932, EHB/NSM). By return mail, Barbour encouraged him to do so, and almost immediately Eiseley departed for Arizona (Barbour to Eiseley, July 18, 1932,
Eiseley left the Scottsbluff excavations before any artifacts were discovered (Barbour and Schultz 1932b:286).

The first artifacts from Scottsbluff were unearthed on August 4, 1932 (Schultz to Barbour, August 4, 1932, EHB/NSM) - over two weeks after Eiseley went to Arizona. The story of Eiseley at Scottsbluff "begging to be sent elsewhere" is therefore untrue, but the observation must also be made that even later Eiseley never displayed any "fear" of becoming involved with this Paleoindian site. He wrote up the Scottsbluff material for his Master's Thesis in Anthropology (Eiseley 1935). And he and Schultz published the results in the American Anthropologist (Schultz and Eiseley 1935) - at the time still the major outlet for archaeological papers.

There are ample reasons why Folsom, and none of the earlier discoveries, was decisive in ending the human antiquity controversy (Meltzer 1991). But Folsom surely ended it, and in doing so cast new discoveries (Custer County, Scottsbluff) and old ones (Meserve) in an entirely different light, a fact well appreciated by archaeologists at the time (Kidder 1936). Contrary to Rogers and Martin (1986, 1987), there was widespread recognition and acceptance of Paleoindian sites in the years immediately after Folsom and long before the advent of radiocarbon dating (e.g., Howard 1935; Roberts 1940; Strong 1933). All this is nicely captured in a letter from Schultz who, having shown the Nebraska Paleoindian artifacts a the American Museum of Natural History, happily reported to Barbour that the Scottsbluff find "is regarded as one of the most important scientific finds of 1932. Geologists, Paleontologists and Anthropologists are all interested" (Schultz to Barbour, January 17, 1933, EHB/NSM).

The archives research reported here was made possible by a grant from the National Science Foundation (DIR-8911249). Work with the Barbour and Schultz papers in Lincoln, Nebraska, was facilitated by the splendid hospitality of R. George Corner. While there, I also had the pleasure of speaking with C.B. Schultz and Michael Voorhies about the history and paleontological research of the Nebraska State Museum.

Helminthological Methods for the Studies of Fossil Vertebrate Dung

Arkady B. Savinetsky and Alexander V. Khrustalev

When birds and mammals inhabit caves and crevices, deposits of dung and food remnants are often accumulated. Radiocarbon dating of such zoogenous remains from caves confirm Pleistocene, Holocene and modern ages of such deposits. Studies of zoogenic deposits consist of radiocarbon, palynological, botanic, and other methods. To obtain additional information on the paleoecology of various biomes, we use a helminthological method for the study of fossil vertebrate dung deposits.

The paleontological recovery of helminth remnants are rare. Nematodes have been found in amber (Taylor 1935). The eggs of Oxyuridae (nematodes) have been found in feces that presumably belong to a lizard representative of Tropidurus (Iguanidae) (Araujo, et al. 1982). These nematodes were recovered...
from dung removed during excavation in a Brazilian cave (radiocarbon dated to approximately 9,000 yr B.P.). Helminth remnants have been found in dung of Alligator (alligator) received from the swamps of Florida (Reinhard et al. 1988). Nematodes were found in preserved carcasses of Spermophilus undulatus (Arctic ground squirrel; Dubinin 1948), Equus sp. (horse; Dubinina 1972), and Bison sp. (bison; Shachmatova 1988) from frozen Quaternary deposits. In recent years paleoparasitology of humans has become popular (Horne 1985; Reinhard, et al. 1988).

The application of the helminthological method became possible with the appearance of radiocarbon dating. This radiometric technique permits the solution to a number of problems concerning the interrelations between wild and domestic animals, distribution of helminthoses by domestic animals (i.e., dislocation of migration passages and centers of domestication), the uses of domestic animals and some other problems. We can acquire information about the paleoenvironment because the life cycle of helminths involves intermediate hosts whose requirements are habitat specific. This is especially true for biogelminths.

Naturally, helminthological analysis of fossil dung is also of interest as far as particular helminthological problems are concerned, such as phylogeny, history of their distribution, and the origin of helminthos centers, among others. Apart from the above, helminthological analysis assists in solving a number of applied problems in the studies of deposits of dung.

To examine the occurrence of helminth eggs (via flotation concentration and inspection under a dissecting microscope) in fossil dung, we studied deposits from different regions in the USSR and Mongolia. Eggs belonging to Nematodirus were found in the dung pellets of the bovid Capra sibirca (goat) from Yaroldzktenian Cave (south Mongolia) (Dinesman et al. 1989). The age of this dung layer is 33,650±1640 yr B.P. (IEMAE-659). Eggs of Oxyuridae were recovered in the Pleistocene (32,210±1130 yr B.P., IEMAE-481) dung of Alticola (mountain vole), and in the Holocene (1,100±80 yr B.P., IEMAE-547) dung of Alticola and Ochotona (pika). Dung of Ovis (sheep) from Turkmenia, USSR, dating 690±130 yr B.P. (IEMAE-780) contain eggs belong to Fasciola.

From north Osetia (Caucasus) we studied the dung deposits (dating 700±110 yr B.P., IEMAE-710) of sheep and Capra cylindricornis (goat) which contained eggs belong to Dicrocoelium, Fasciola, Trichuris, and Trematoda. Additional dung of Capra cylindricornis dating 810±80 yr B.P. (IEMAE-736) contained eggs of Capillaria and Dicrocoelium.

These results indicate that the eggs of helminths can be preserved for thousands of years. However, most of the remains are eggs of trematodes and nematodes with dense and thick shells.

Paleoenvironments: Plants

Preliminary Analysis of a Late Glacial Pollen Record from Cloquet Lake, Lake County, Minnesota, USA

James K. Huber

Palynological investigations of a core from Cloquet Lake, Lake County, Minnesota are currently being undertaken to aid in the understanding of Paleoindian occupation of the area. Preliminary pollen analysis indicates that the pollen sequence at Cloquet Lake records local and regional vegetational change during the late glacial/postglacial transition. The headwaters of the Cloquet River, Cloquet Lake are located approximately 90 km north of Duluth, MN (91°30'W, 47°30'N)

The 438-cm core extracted from near the center of the lake is composed of two distinct stratigraphic zones separated by a 3-cm thick gravel layer. The upper 397 cm consists of detrital gyttja; below the gravel layer (400-438 cm) is silty clay (Figure 1).

The pollen diagram from the site has been divided into three pollen-assemblage zones representing the late glacial and early postglacial history of the watershed. These zones are comparable to the pollen-assemblage zones defined by Cushing (1967) and Wright and Watts (1969) for northeastern Minnesota.

Zone I is characterized by more than 50% nonarboreal (NAP) pollen (Figure 1). The dominant NAP types are sedge (Cyperaceae), ragweed (Ambrosia-type), wormwood (Artemisia), and grass (Gramineae). Spruce (Picea) and willow (Salix) are most abundant arboreal (AP) pollen types. This zone suggests a shrub tundra-like environment with occasional stands of spruce or individual spruce trees.

Zone II is marked by the maxima and subsequent decline in spruce as pine (Pinus) increases; NAP also decreases (Figure 1). Birch (Betula) also increases
in the upper part of this zone. Most of the pine grains are Diploxylon-type. The pollen spectra in Zone II indicate a conifer forest.

Diploxylon-type *Pinus, Picea*, and alder (*Alnus*) are the dominant AP taxa found in Zone III (Figure 1). NAP is low, 15% or less. Currently the upper limit of this zone is undefined pending further pollen analysis. Zone III indicates that a mixed conifer-hardwood forest is developing in the Cloquet Lake watershed.

Pollen analysis of the Cloquet Lake core is continuing, and radiocarbon dating of the core is planned. Analysis of algae recovered in conjunction with the pollen is also being undertaken. When this investigation is finished, the results will provide a more complete understanding of late glacial vegetational

---

A Paleolimnological Example of Modulated Succession from Southeast Venezuela, and its Significance in Pleistocene Paleoecology

Valenti Rull and Teresa Vegas-Vilarrúbia

Most frequently, Pleistocene records are interpreted in paleoenvironmental terms. However, they may provide more information, related with ecological successions.

To exemplify these type of ecological studies, we analyzed a recent pollen sequence from Lake Carinapay (4°37'N, 60°57'W). The lake is shallow and with well-developed macrophytic vegetation, characterized by Sagittaria guayanensis, Sagittaria sp., Xyris, Utricularia, and several Cyperaceae. Zygnema and Mougeotia (Zygnemataceae) also occur. The core studied (1.90 m long) was subdivided into 19 levels, from 1 (top) to 19 (base). A surface sample (0) represented the present-day conditions. Ages were deduced by correlation with \(^{14}C\) dated sequences (Rull 1990). Common methods of pollen analysis (Faegri and Iversen 1989), with some modifications (Salgado-Labouriau and Rull 1986; Rull 1987) were used.

Based on the variations of algal remains, we established a ratio (P/L) between planktonic (Botryococcus and Tetraedron) and littoral (Zygnema, Debarya and other Zygnemataceae) ones, to estimate the relative water level (WL). The variations of P/L were slow and continuous, showing two phases of low WL (1,000-800 and 600-400 yr B.P.), and two of high WL (800-600 and 400-0 yr B.P.). The responses of macrophytic community were analyzed by defining assemblages, through clustering of samples according to the abundances of

Valenti Rull, MARA VEN, Exploration (Palynology), P.O. Box 829, Caracas 1010-A, Venezuela.
Teresa Vegas-Vilarrúbia, Central University of Venezuela Biology School, Laboratory of Limnology, P.O. Box 47106, Caracas 1040, Venezuela
Cyperaceae (CYP), Myriophyllum-type (MYR), Sagittaria guayanensis (SGY), Sagittaria sp. (SSP), Nuphar (NUP), and Xyris (XYR) pollen. The euclidean distance and the weighted centroid agglomerative method were used and six assemblages were obtained: A (SGY dominant, CYP subdominant), B (CYP-SGY co-dominant), C (CYP dom., SGY subdom.), D (CHP only), E (CYP dom., NYR-SGY subdom.), and F (CHP dom., SSP subdom.). A transfer matrix was built, and the probabilities of between-stage moving were computed. The maximum probabilities corresponded to the stopping in assemblage B (p = 0.16), stopping in A and moving from A to C (p = 0.11). Other observed variations have equal probabilities (p = 0.06), except those not observed (69%). The total probability of stage A is p = 0.33, followed by C (p = 0.28), and B (p = 0.22). The more stable interval occurred between samples 15 and 9, where the probability of B is p = 0.75, but a general, largely oscillating trend could be easily seen. Furthermore, retrogressions and circular trends could be observed, thus indicating that the process in non-linear. Complexity, as measured by the Shannon-Weaver index of diversity was also oscillating. Minimum diversity (H = 0) corresponded to the pioneer stage D, whereas the more complex coincided with the more ephemeral, i.e., those with low total probability (H = 1.80-1.98 for E and 2.10 for F). On the contrary, the more frequent assemblages were the less complex, which attained the following mean values of H: 1.19 (A), 1.33 (B) and 1.28 (C). Therefore, the sequence studied did not show a directional autoorganizational tendency from simple to more complex seral stages—the classical concept of ecological succession (Odum 1971; Margalef 1977).

Rull (in press) differentiates among undisturbed and modulated successions, the former being those developed under a constant environment, whereas the latter are submitted to oscillating external factors which cause continuous reorganizations in the involved biocenose. A common feature is that succession (s. 1.) involves persistence of the community into its attraction domain (Holling 1973); if the biotic tolerance is overcome by an environmental shift, a substitution (change of attraction domain, i.e., change of community) occur. The case-study presented falls in the category of modulated succession, and supports the unsuitability of the “climax” concept (Flenley 1979), as well as the hypothesis of a maintained disequilibrium between environment and living communities (Davis 1984; Delcourt and Delcourt 1983).

Long Pleistocene sequences are probably full of undisturbed and modulated successions which are commonly ignored because of the sampling design and the research objectives. Paleoclimatic research is concerned with notable ecological changes, commonly substitutions, from which it is possible to derivate significant environmental shifts. However, Paleocology is the Ecology of the past (Birks and Birks 1980), thus not only including the study of past environments, but also of past biotic relationships. Furthermore, sampling for paleoclimatology must take into account minor ecological reorganizations and trends, in order to avoid incorrect deductions from samples taken in different stages of successions, which are non-predictable, and most probably non-comparable. Similar errors are, for instance, to deduce significant sedimentary
changes from sampling designs based only on the within-samples distance and ignoring facies succession within single sedimentary units.

Detailed ecological analyses of selected short Pleistocene sequences and comparison with modern analogues like Carinapay are thus necessary, in order to avoid these problems.

Historic Bovid Teeth from Gardiner, Maine

Harold W. Borns, Jr. and Clayton E. Ray

On September 26, 1845, Sir Charles Lyell examined fossils in the cabinet of Mrs. Frederic Allen of Gardiner, Maine. Among these were four teeth subsequently identified by Richard Owen as those of American Bison (Bison) (Lyell 1849:44). Some of the teeth were figured by Packard (1867, plate VII, figs. 18, 18a, 18b) and by J.A. Allen (1876, pl. XII, figs. 13-15). J.A. Allen (1876:88-91, and note following caption to plate XII) provided a through history of the find to that date (including Owen’s disavowal of his earlier identification), and concluded that the teeth represented modern domestic ox, Bos taurus, intrusive into the Pleistocene clays. The specimens have attracted very little later attention, excepting notably from G.A. Allen (1920:161) and Hay (1923:24, 292), both of whom were inclined to accept J.A. Allen’s assignment to Bos taurus.

Three of the teeth from Mrs. Allen’s estate were deposited in the collections of Bowdoin College, Brunswick, Maine, and one in the Museum of the Boston Society of Natural History. This last tooth, the one depicted in J.A. Allen’s fig. 13, was located recently by one of us (Borns) in the collections of the Boston Museum of Science, the successor to the Boston Society of Natural History, under that society’s number 15198. We have not as yet been able to confirm the current presence of the other teeth at Bowdoin College.

Reassessment of the published evidence indicated that the field data were uncommonly extensive and explicit for the time of collection (1837), including a written deposition by the collector (J.A. Allen, 1876:90), which made it difficult to dismiss the specimens summarily as the product of recent intrusion. The extreme rarity of evidence of Pleistocene terrestrial mammals in New England, and their potential importance as prey for humans populating the recently deglaciated terrain, stimulated our desire to resolve the identity and age of these remains.

Harold W. Borns, Jr., Institute for Quaternary Studies, University of Maine, Orono, ME 04469
Clayton E. Ray, Department of Paleobiology, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560
Accordingly, one of us (Ray) reexamined and compared the one available tooth with known *Bison* and *Bos* again, as with Allen, inconclusively, although inclined toward *Bos*. Particularly, with the potential ramifications attached to its identification, no decision seemed defensible on morphological grounds alone. A 14C date using the AMS technique seemed the only realistic means of laying the problem to rest.

The Boston Museum of Science generously gave permission to sacrifice a small part of the tooth for dating; the Arizona AMS Facility, University of Arizona, agreed to analyze the sample; and funding was provided by the Department of Paleobiology, National Museum of Natural History, Smithsonian Institution.

The specimen, University of Arizona sample AA-5275, yielded an age of less than 113 years, even younger than the 153 years since date of collection. Thus, there seems now to be no reason to doubt the teeth represent modern domestic *Bos taurus*. The availability of the AMS technique affords the possibility of dating specimens of equivocal or unknown age, thereby resolving previously intractable problems with historic specimens, and increasing the scientific significance of specimens with inadequate data.

A record for Caracara from the Late Pleistocene of Nebraska

Robert M. Chandler and Larry D. Martin

The identification of a partial left tibiotarsus (UNSM 69609) as that of a caracara (Falconidae: Polyborini, Polyborus aff. P. prelutosus Howard 1938) is the northernmost occurrence for a caracara in the fossil record (Brodkorb 1964; Lundelius et al. 1983). Today small populations of caracaras can be found in areas in Arizona, Florida, and Texas (Palmer 1988). Pleistocene records for caracara include those states listed above plus California and New Mexico.

The partial tibiotarsus (UNSM 69609) is within the size range and relative proportions of the northern subspecies of the living caracara Polyborus plancus cheriway and the fossil species P. prelutosus Howard. The less angular tendinal bridge, the shape of the shaft, and the location where the fibula ankylosis to the shaft of the tibiotarsus are diagnostic for caracaras distinguishing them from falcons and hawks. The fossil (UNSM 69609) and the southern subspecies, P. p. plancus, differ from the northern subspecies, P. p. cheriway, by having a symplesiomorphic character: the intermuscular line on the anterior surface extends proximad to the fibular crest. Howard (1938) found the tibiotarsus of P. prelutosus to be more like plancus than cheriway qualitatively.

The fossil is from the Angus Local Fauna (LF) in Nuckolls County, Nebraska, which is late Irvingtonian, Sheridanian subage (Martin and Schultz 1971; Lundelius et al. 1987). A large avifauna is represented in the Angus LF which includes grebes, ducks, hawks, grouse, a crane, and avocet, a curlew, a dove, a woodpecker, and numerous perching birds.

The Angus LF was recovered from sediments deposited in a small pond that was closely associated with a fluvial system. Numerous fish remains were recovered along with aquatic molluscs. A diverse mammal fauna includes Mammutus (mammoth), Mammut (mastodon), peccary, camel, and Equus (horse). Small mammals include forest forms like the red-backed vole (Clethrionomys) and the southern bog-lemming (Synaptomys). Also represented are an ancestral Cynomys (black-tailed prairie dog), several ground squirrels, a pocket gopher, and a kangaroo rat. These rodents and the caracara would have required more open country. Therefore, the associated vertebrates in the fauna gives a parkland environmental picture.
We would like to thank R.G. Corner, R.M. Hunt, Jr., and M.R. Voorhies for the loan of the Angus LF fossil birds. R.M. Mengel and M.A. Jenkinson made the Charles Dean Bunker Memorial Skeleton Collection available to us for this study.

Taphonomic Analysis of the Burning Tree Mastodon

Daniel C. Fisher, Bradley T. Lepper, and Paul E. Hooge

Comparative taphonomic studies of late Pleistocene proboscideans may provide critical insight into the nature of the fossil record from this time period (Fisher 1984; Graham and Kay 1988). An opportunity to document taphonomic patterns for Mammut americanum (American mastodont) emerged in December, 1989, when a dragline excavating a pond in Licking Co., Ohio struck the cranium of the Burning Tree mastodon (Lepper 1990). Manual salvage excavation (recorded by photographs and video) revealed additional skeletal material.
undisturbed by mechanical excavation. Bones were preserved within peat that formed under anaerobic conditions in a small lake occupying a local depression on late Wisconsinan till. They occurred in three clusters (separated by 2-4 m), each consisting of tightly articulated units and multiple, disarticulated bones. The first included the cranium, mandible, articulated inominates and sacrum, both scapulae, thoracic vertebrae, and left hindlimb elements; the second included two articulated sets of thoracic vertebra, multiple ribs, and an approximately 60 by 12 cm cylindrical mass of plant material later confirmed as gut contents (Lepper et al. in press); and the third included articulated cervical vertebrae, articulated carpals, both humeri, additional forelimb elements, and the right patella. The skeleton lacks only the thyrohyoids; left patella; right femur, tibia and fibula; most phalanges and sesamoids; and all but two (ca. 10th and 14th) caudal vertebrae posterior to the 8th. Extensive probing, screenwashing, and manual spreading of sediment revealed little additional mastodont material. High recovery of even small elements suggests that missing mastodont bones were not present at the site. A stratigraphically consistent set of 12 radiocarbon dates and preservation of easily oxidized sedimentary pigments indicate little or no bioturbation. Dates on gut contents were 11,450±70 (Pitt-0832) and 11,660±120 yr B.P. (Beta-38241/ETH-6758).

This mastodont was an almost fully grown male (molar stage ca. XIX; Laws 1966). Incremental laminae in tusk dentin (Fisher 1988) and the suite of taxa represented by seeds in the gut contents indicate an autumn death. The bones show no evidence of subaerial weathering, and viable enteric bacteria have been isolated from the gut contents (Lepper et al. in press), indicating early introduction into anaerobic conditions. Despite the relative completeness of the skeleton, apparent drag marks on the last three right ribs imply that the carcass was partly disarticulated and then transported to the lacustrine setting from another location. Lateral surfaces of these ribs show gouges oriented normal to rib axes (Figure 1). Under SEM, the gouges (accompanied by some probable cutmarks) are clearly postdated by innumerable, finer, parallel striations that cover much of the surrounding bone surface. These finer marks could have been made by abrasion against a coarse clastic substrate, but their overwhelming parallel attitude, invariant from one rib to the to the next, argues against trampling (Behrensmeyer et al. 1986), especially in the fine, lake sediments. In situ mechanisms involving moving water or ice are incompatible with the low energy depositional setting and autumn season of death, respectively. Whatever caused the gouges, the fine striations probably record dragging of an articulated unit across a coarse substrate.

We have difficulty explaining these observations entirely in terms of nonhuman agents. Hyenas sometimes cache carcass parts in water (Kruuk 1972), and some North American Pleistocene carnivore could have shown analogous behavior, but mastodont size, patterns of bone distribution, and relative skeletal completeness challenge this explanation. There are tooth impressions at the distal ends of some ribs, but these suggest nothing larger than a medium-sized canid. We also note symmetrical treatment of some bones. Metacromion
processes, though present, are broken from scapulae, and dorsal and posterior scapular epiphyses show nearly identical patterns of gouges (Figure 1), some

Figure 1. Distribution of gouges on several skeletal elements of the Burning Tree mastodont. Solid outlines show margins of gouges; interior lines show orientation of deep grooves within gouges; and open arrows indicate predominant, local direction of production of gouges. A, B, left and right dorsal scapular epiphyses, in lateral aspect; C, D, left and right posterior scapular epiphyses, in posteromedial aspect (asymmetry of gouge direction may relate to death orientation of carcass); E, right ribs 17-19, in dorsal aspect.
with internal striae. Such gouges were probably made during muscle detachment (nearby cavities in the bone retain sediment exotic to the lacustrine setting). The dorsal iliac border is modified similarly, and symmetrically. This symmetry has an anatomical component, but it also reflects highly structured behavior. Representation of hindlimb elements proximal to the tarsus (left longbones without patella; right patella without longbones) also suggests symmetry in dissociation of patellae from longbones, as may have occurred during removal of knee extensors. Many aspects of the condition and distribution of individual bones and the overall structure and context of the site replicate patterns at other mastodont sites such as Pleasant Lake and Heisler (Fisher 1984, 1987). Fisher (1989) has suggested that these occurrences represent butchery of mastodonts by Paleoindians and caching of carcass parts in ponds for later recovery and processing. We recognize the complexity of taphonomic inference with limited benefit of Recent analogues, and are committed to continued investigation of alternative explanations for the Burning Tree and other sites, but at present, the hypothesis of meat-caching by Paleoindians appears to be the simplest interpretation of our observations.

Preliminary Report on the Fauna of Pendejo Cave, Otero County, New Mexico

*Arthur H. Harris*

Pendejo Cave, located in south-central New Mexico about 21 km east of Orogrande, contains both faunal and archaeological material. The material reported here was excavated during 1990. The upper stratigraphic levels contain Archaic archaeological material that continues downward to as deep as Zone F (MacNeish 1990; Turnbull 1990). Below the Archaic levels, extending down into Zone O, are plant and faunal remains associated with stone and bone items interpreted by the excavator, Richard S. MacNeish, as human artifacts; included here is material from layers 14C dating from 25,420±560 yr B.P. to >34,000 yr B.P. (UCR-2495) (MacNeish 1990, per. comm. 1991; Turnbull 1990). Faunal remains under these circumstances are of obvious interest.

At this time, only coarse-screened material has been seen, preparation of specimens has been minimal, and the total number of elements somewhat scanty; thus identifications should be considered somewhat more tentative than average. Many of the bones of extinct mammals appear to be heavily burned, and ash layers occur to the bottom of the section in Zone O (MacNeish 1990).

Extralimital and extinct taxa identified are desert tortoise (*Gopherus cf. agassizi*), western vulture (*Coragyps occidentalis*) prairie chicken (*Tympanuchus pallidicinctus*), Conkling’s roadrunner (*Geococcyx californianus cf. conklingi*), magpie (*Pica pica*), Aztlan rabbit (*Aztlanolagus agilis*), Nuttall’s cottontail (*Sylvilagus nuttalli*), Gunnison’s prairie dog (*Cynomys cf. gunnisoni*), northern pocket gopher (*Thomomys talpoides*), bushytailed woodrat (*Neotoma cinerea*), vole (*Microtus sp.*), lion or, possibly, short-faced bear (*Panthera leo atrox* or, possibly, *Arctodus simus*), Mexican horse (*Equus conversidens*), larger horse (*Equus sp.*, possibly *E. niobrarensis*), large-headed llama (*Hemiauchenia cf. macrocephala*), large camel (*Camelops sp.*), and small pronghorn (*cf. Capromeryx*). The remaining faunal members, consisting of some 32 taxa of amphibians, reptiles, birds, and mammals, either occur in the area today or likely did so historically.

Arthur H. Harris, Laboratory for Environmental Biology, University of Texas at El Paso, El Paso, TX 79968.
The occurrence of probable Archaic artifacts as low as Zone F suggests an age between 6,300 and 8,000 yr B.P. (Turnbull 1990). Presence of the small, western horse in Zone E and of moderate-sized horse and extinct llama in Zone F probably indicate some mixing of levels, as does presence of the northern pocket gopher in Zone D.

Two species of horse have been identified from Zone G, but no other extinct or extralimital taxa. A date of 16,440±650 yr B.P. (UCR-2504) may apply to Zone H or I (MacNeish 1990). Starting with Zone H, both extinct and extralimital taxa are moderately common, suggesting that Zones H through O are fairly certainly Pleistocene, agreeing with 14C dates.

Remains of the Aztlan rabbit are rare in Zone M, but moderately common in the lowermost deposits, Zone O. This extinct rabbit probably is a marker for mid-Wisconsinan time in this part of New Mexico (Russell and Harris 1986). Desert tortoise in this region appears to have occurred in mid-Wisconsinan and again in post full-glacial times (Van Devender et al. 1976); its presence in Zone M, well below the uppermost Pleistocene material, indicates mid-Wisconsinan conditions.

The identified extralimital taxa occur elsewhere in the mid and late Wisconsinan of southern New Mexico and indicate cool summers and more effective moisture (Harris 1987, 1989). The desert tortoise probably requires relatively mild winter temperatures (Van Devender et al. 1976).

The relatively small number of recovered elements thus far examined is insufficient for detailed analysis of faunal changes within the Pleistocene segment. What is clear at this point in the investigations, however, is that bone and stone items believed by MacNeish to be tools are associated with a typical Pleistocene fauna and that some go back into the mid-Wisconsinan in conformity with the radiocarbon dates.

I thank Dr. Richard S. MacNeish for the opportunity to examine this material and for information concerning the site.

**The DeLong Mammoth Locality, Black Rock Desert, Nevada**

*Stephanie D. Livingston*

At least a dozen concentration of fossil bones and lithic artifacts occur within a diffuse lithic scatter that covers extensive areas along the eastern edge of the Black Rock Desert (BRD) playa in northern Nevada (Clewlow 1968, 1983; Pedrick 1983; Dansie et al. 1988). Artifact styles identified in the lithic scatter include fluted points similar to the Clovis type dated elsewhere between 11,000 and 11,500 yr B.P.; Great Basin Concave and Stemmed projectile point types and crescents, estimated to be at least 8-9,000 years old; and square-based projectile point types referable to the Cody Complex (Wallmann and Amick 1991), which is dated from 8,500-10,000 yr B.P. in the southern Plains (Thurmond 1990); as well as the more common post-Mazama great Basin types (Clewlow 1968; Gruhn and Bryan 1988; Roney 1979). Taxa represented in the various bone concentrations include mammoth (*Mammuthus*), bison (*Bison antiquus* and *B. bison*), camelids (*Camelops cf. hesternus*), carnivores (*Smilodon* and *Canis lupus*) and possibly ground sloth (*Glossotherium harlani*) (Clewlow 1983), as well as numerous extant species.

The occurrence of bones of extinct mammals with lithic artifacts referable to pre-Mazama complexes leads to speculation regarding the relationship between people and the extinct mammals. The chronology of artifact types and estimated time of extinction of the large mammals, both determined from other areas, indicate that people and extinct mammals coexisted on the BRD. Most observed BRD assemblages, however, could be the result of lithic concentrations deflating onto older deposits containing vertebrate remains. Attempts to obtain absolute dates for BRD bones have not been satisfactory and geomorphological evidence of contemporaneity is unclear at many localities. No local association of artifacts and vertebrate remains exposed on the surface of the BRD has been demonstrated to be other than fortuitous.

The DeLong Mammoth Locality (DML) on the east edge of the BRD provides an opportunity to examine site-formation processes responsible for the co-occurrence of artifacts and vertebrate remains along the edge of the BRD playa. The DML consists of an extensive (1,000 by 600 m) surface bone scatter bounded by dunes on the north and south, and a small, north-south-trending channel and
more dunes on the west. Seven, and possibly eight, vertebrate families are represented in the surface bone: Anatidae, Leporidae, Cricetidae, Equidae, Cervidae, Antilocapridae, Elephantidae, and possibly Camelidae. The core bone concentration is approximately 75 by 50 m and consists of primarily mammoth bone. An additional taxon, a large carnivore, was recognized in the faunal material from one of two test units excavated in the main bone concentration. There are at least three mammoth in the main concentration, as determined from size and maturity estimates for exposed specimens. All three apparently died young.

East of the channel demarcating the eastern extent of the DML bone concentration is a large dune that is the nucleus of an extensive lithic artifact concentration. The numerous lithic flakes and biface fragments found among the surface bone of the DML are most likely related to human activities associated with the dune, events which probably post-date deposition of the DML bone. No lithic artifacts were found below the surface in the excavation units.

Paleotopography of the DML is being reconstructed using satellite imagery and aerial photography, soil conductivity measured with a non-contacting terrain conductivity meter and a bore-hole conductivity meter, sediment augering, and profiles of the two test excavation units. Data obtained from these sources indicate that the current, extremely flat playa edge, cut by occasional small channels and flanked by dunes, is similar to past conditions, but the locations of channels have varied through time. The mammoth bone is lying on a shallowly buried surface and in a buried channel.

Agenbroad (1984) observed that in a sample of 856 North American mammoth localities for which geologic environment is reported, 73 % are in environments associated with water, such as stream channels, flood plains, marsh or bog environments, springs, and lacustrine deposits. Two or more individuals have been found in at least 21 of those localities. He argued that multiple-mammoth localities probably represent environments of post-mortem events more closely than the habitat of the living animals, with the exception of the Hot Springs Site in South Dakota where more than 30 adult mammoth were apparently trapped alive. Current interpretation of known assemblages is that most multiple-mammoth localities represent post-mortem bone accumulation by carnivores or geological processes, or human predation events.

Human involvement in the deposition of extinct animals in localities similar to the DML on the BRD has been suggested based on degree of disarticulation and dispersion of skeletons and orientation of elements (e.g., Dansie et al. 1988). The effects of animal behavior and ecology, and fluvial processes, have not yet been assessed in the BRD playa sites because the behavior and ecology of Pleistocene animals is unknown, as is the prehistoric fluvial regime of the BRD.

Comparisons of paleofaunas containing extinct taxa with modern bone assemblages of similar and related taxa deposited in similar environments provide a basis for approximating the conditions under which assemblages exhibiting particular characteristics were accumulated. Conybeare and Haynes (1984; see also Haynes 1985,1988), suggested that elephant die-off at a natural water source in Zimbabwe following an unusually severe drought might provide
an analog for fossil proboscidian assemblages. The DML bone distribution is reminiscent of the bone scatters described by Conybeare and Haynes. Concentration of partially articulated and disarticulated mammoth bone in and adjacent to a small channel, the apparent youth of the mammoth, and the diversity of the rest of the faunal assemblage supports the possibility that the DML animals represent late Pleistocene faunal die-off along the receding edge of a pluvial lake.

Demonstration that fossil bone localities on the BRD, in areas that were inundated during pluvial maxima, represent drought-induced die-off similar to observed modern drought-induced die-off, could provide information important to understanding the extinction of Pleistocene animals. At a minimum, comparison of the DML with modern catastrophic death assemblages indicates the need for caution in interpreting terminal- or post-pluvial fossil animal localities in erosional environments that have witnessed extensive human use through time. Co-occurrence of artifacts with disarticulated bone in localities such as the DML is not necessarily indicative of human involvement in the death and deposition of the animals.

The investigations described here were conducted by the DRI-QSC, the BLM, and dedicated amateurs funded by Mrs. Betty Stout, EPSCoR, and the Lander Foundation. These studies were guided by the late Dr. J.O. Davis, whose vision will be sorely missed.

Late Pleistocene *Hemiauchenia* from North Central Kansas

*Brad Logan, Larry D. Martin and John F. Neas*

Skeletal remains of a lamine camelid identified as *Hemiauchenia* sp. (KUVP-103561) were recovered from a late Pleistocene deposit on the northern shore of Lovewell Reservoir, Jewell County, Kansas. The reservoir is on White Creek, a tributary of the Republican River. Discovery of the remains occurred in October 1989 during an archaeological survey of the reservoir. Recovery of exposed and erosion-threatened bones at that time was followed in May 1990 by complete excavation of the specimen (Logan 1990).

The remains were found within a silt deposit at a depth of 1.2 m in a 2.5 m high wave-cut exposure. The stratigraphic unit containing the llama remains has been radiocarbon dated to 13,410±300 yr B.P. (Tx-3666). The dated material was a bulk sample of organic-rich sediment, with wood fragments, extracted with a truck-mounted coring device from an area on the adjacent beach less than 100 m from the find (Rolfe Mandel, University of Nebraska, Omaha, personal communication).

Elements recovered and their position are: 1) Left Forelimb: humerus (fragment of head to distal trochlea), ulna (proximal-olecranon and trochlear notch), radius, magnum, trapezoid, unciform and scaphoid, cuneiform, lunar (anterior fragment), metacarpus (proximal); 2) Right Forelimb: humerus

(diaphysial fragment, deltoid tuberosity and spiral groove), radius (distal), scaphoid (anterior half), cuneiform, unciniform metacarpus (proximal- 2 pieces); 3) Left Hindlimb: femur (complete), tibia (tuberosity only); 4) Hindlimb (position unknown): metatarsal (distal), proximal phalanx of pes, proximal phalange, metapodial; 5) Unknown limb: 2 fragments; 6) Axial Skeleton: 8 thoracic vertebrae, 3 lumbar vertebrae, ribs (numerous shaft fragments).

The remains include only postcranial elements from what appears to be an individual. conspicuously absent are the skull and axial parts such as scapulae, cervical vertebrae, sacrum and pelvis. Neither are there any articular ends of ribs in the assemblage, despite the presence of most of the thoracic vertebrae. Of elements represented, only the femur was found unbroken. Articular ends were intact but diaphyses were fragmented. Some elements of the specimen probably have been lost to wave action since inundation of the lake in the 1960s.

What force accounts for the breakage and positioning of the bones cannot be identified readily. The late Pleistocene date of the specimen and the presence of Clovis hunters in the area (e.g., at 14JW310 ca. one km east of the site), raised the possibility that Paleoindians might have dispatched and butchered the animal. No cultural material was found with the remains, nor are any cut-marks visible on the bones. It is unlikely that hunters broke the long bones for marrow since several articular ends retain more diaphysial bone than is typical of marrow-processed elements. Though broken and moved about, the bones remained within an area of 1.56 by 0.63 m. We can be reasonably certain that they have not been transported any great distance from the site of the animal’s death. Some pieces were articulated (i.e., the distal metatarsal and proximal phalanx) or nearly so (i.e., the lumbar vertebrae). No clear evidence of carnivore gnawing or breakage is discernible so predatory behavior is not indicated.

That the bones were broken while in the green state is shown by the spiral fractures of several long bone fragments. This may indicate trampling by other animals. The presence of weathering cracks and weathered surfaces of the bones suggest that they remained on the surface for at least a year before burial. In at least one instance (the distal left metatarsal with articulated phalanges and sesimoids) the bones must have been held in place by ligaments and skin until burial. Strangely, the distal phalanges were missing from this specimen. Severe root damage to the bones suggests a relatively slow burial process. Natural death followed by trampling, a short period of exposure, and subsequent burial appears to be the only sequence of events that accounts for all observations, including lack of predation-related signatures, fragmentation of fresh bone, presence of weathering cracks, slight dispersal and unit articulation, good preservation, and lack of size-grading or sorting by water action.

Although most of the bones have sustained major damage, the characteristic shape of the proximal ligamental scar on the phalanges and its small size identify it as a member of the camel tribe Lamini (Breyer 1974). On biogeographic grounds, it is likely that the remains are those of *Hemiauchenia* as are probably those of the only other late Pleistocene lamine occurrences in
Kansas. The latter are two unpublished finds, both isolated proximal ends of first phalanges. The most diagnostic criteria are to be found in the proportions of the metapodials (Webb 1974). Unfortunately, the two metapodials from Lovewell are not complete. One reconstructed ulna gives a length of over 550 mm. It is within the range for *Hemiauchenia macrocephala* but would appear to be too long for *Paleolama mirifica*, the other possible lamine. *Hemiauchenia macrocephala*, the large-headed llama, was a relatively long-legged, highly cursorial plains-dweller that probably fed on grass (Kurten and Anderson 1980). The Lovewell specimen, the most complete late Pleistocene Lamine camel yet collected in the Central Plains, provides insight into the environment and faunal biogeography of that region.

We thank Steve Holen and Bob Blasing for their role in the discovery and recovery of the specimen and the Bureau of Reclamation, Grand Island, Nebraska for its support of our salvage of the Lovewell llama.

**Preliminary Report of the Pleistocene Mammals of the Valley of the Axamilpa River, near Tepeji de Rodriguez, Puebla, Mexico**

*Adriana Torres Martinez and Larry D. Agenbroad*

The valley of the Axamilpa River, near Tepeji de Rodriguez, in the state of Puebla, is a newly discovered Quaternary fossil locality (Figure 1). Alluvial

Adriana Torres Martinez, 33 Bellas Artes Cuernavaca, Morelos, Mexico.
Larry D. Agenbroad, Box 6030 Department of Geology, Northern Arizona University, Flagstaff, AZ 86011.
Paleoenvironments: Vertebrates

and lacustrine units have been dissected by the river, providing numerous exposures containing remains of Pleistocene flora and fauna.

Figure 1. A location map of the Axamilpa River deposits, with a schematic cross-section, showing the relationship of the Quaternary deposits with older, Tertiary limestones (a) containing fossil fish, birds, reptiles, and mammal tracks; Tertiary/Quaternary travertines (b) with gastropods; and Quaternary lacustrine deposits (c, d) and alluvium (e) containing Pleistocene mammals.
At least five genera of large, extinct, Pleistocene mammals exist in these deposits, including the first occurrence of *Mammuthus columbi* (mammoth) reported for the state of Puebla along with a specimen of *Cuvieronius* (mastodon) discovered during the 1990-1991 field season. Faunal elements represent remains of reptiles, Testudinidae (turtle), and mammals: *Mammuthus columbi, Cuvieronius, Equus* (horse; possibly including: *E. caballus, Equus tau,* and *Equus asinus*), *Bison* sp. (bison), *Paleolama* (llama), and *Glyptodon* sp. (Torres-Martinez 1986, 1988).

The region of investigation comprises an area of at least 6 km², located approximately 4 km northwest of the village of Tepeji de Rodriguez, near the geographic coordinates 18°30'N and 98°7'E. The deposits are at an altitude of 1750 m above sea level. The modern climate is semi-arid, with some semitropical variants. The deposits are contained in a topographic depression containing the Axamilpa River, which is tributary to the Atoyac River, draining a portion of the eastern Sierra Madre Mountains. The Quaternary deposits are superimposed on Cretaceous marine and Tertiary lacustrine sedimentary sequences (Padilla y Sanchez 1973).

The Quaternary deposits of the Axamilpa represent at least two, and possibly three, periods of deposition. Approximately 16 m of older Quaternary sediments (siltstone and marl) unconformably overly the older deposits, and contain plant impressions. These deposits have been tilted, and are overlain by up to ca. 30 m of alluvial sands, silt and gravels, tufa, lacustrine deposits composed of marls, siltstone, and carbonaceous evaporites including caliche and travertine.

The deposits containing the majority of the megafaunal remains are alluvial and lacustrine terraces formed, and abandoned by dissection of these deposits due to the river downcutting to its present level. Initially, five localities containing Pleistocene mammals were discovered. An additional six localities were investigated during the interval December 1990 - January 1991.

Preliminary pollen studies from locality 4 report the presence of *Pinus,* Gramineae, and *Alnus,* interpreted to represent an open woodland that is currently more northerly or at higher elevations in Mexico (Rzedowski 1978). A bulk soil sample collected from below the *Cuvieronius* bone radiocarbon dated to 13,710±430 yr B.P. (Beta-45825).

Paleoenvironments: Geosciences

Geomorphic Processes and the Archaeological Record in Small Basins of the Kansas River System

Alan F. Arbogast

A geoarchaeological model for the Kansas River basin has been proposed by Johnson and Logan (1990) which synthesizes the archaeological record and relates it to ongoing geomorphic processes in the basin. Results of the study indicate the cultural record ranges from Paleoindian through Historic and there is a high probability of locating these cultural components buried in situ beneath certain alluvial surfaces. Evidence suggests that erosion has removed much of the record, and that valley fills appear to decrease in age westward across the basin. According to Johnson and Logan (1990), however, spatial and temporal distributions are probably biased since much more is known stratigraphically about the Kansas River basin proper than smaller basins within the system.

Because of the present bias toward the trunk stream, recent research has focused on Wolf Creek, a small (163 km²) basin located in the center of the Kansas River system (Figure 1). Detailed study of alluvial stratigraphy and terraces has revealed the relative and absolute ages, as well as the textural composition of these features in the basin. Stratigraphic evidence suggests that the entire cultural record may be preserved within alluvial deposits of this small watershed.

Results of the study indicate that a single terrace (T1) dominates the basin and is underlain by silt and silt loam alluvium, ranging in age from early through late Holocene. Early to mid-Holocene fill has been recognized only in the upper reaches of the basin’s small tributaries, where it is buried by nearly three meters of late Holocene alluvium. Conversely, late Holocene fill is found throughout the basin, e.g., humates from an organic-rich deposit at the base of late Holocene alluvium yielded a radiocarbon age of 2,970±80 yr B.P. (Tx-6795).

Alan F. Arbogast, University of Kansas, Department of Geography, 213 Lindley Hall, Lawrence, KS 66045
Stream entrenchment (up to 4 m) and lateral cutting has created up to four ill-defined terraces beneath T1 surface. In some portions of the basin, lateral cutting has been very active, removing up to 40% of late Holocene fill, whereas in other areas the effects of this process have been minimal.

Three distinct episodes of soil formation, reflecting episodes of relative floodplain stability, have been recognized thus far. Radiocarbon age determinations from the upper 5 cm of buried A horizons in these paleosols reveals that soil formation terminated shortly after about 6,770±110 yr B.P. (Tx-6914) in early to mid-Holocene fill and about 1,750±70 yr B.P. (Tx-6959) and 1,250±60 yr B.P. (Tx-6960) in late Holocene alluvium. Each of the paleosols exhibit simple A/C profiles, indicating that pedogenic process were of short duration, i.e., less than 1,000 years.

The results obtained from the Wolf Creek basin have significant implications regarding preservation of the archaeological record in similar sized basins in the Kansas River system. Certainly, the focus of any survey should be paleosols, which represent the best potential for cultural artifact concentrations in these basins (Ferring 1986). While Paleoindian and early to mid-Holocene Archaic sites were likely eroded sometime between ca. 6,500 and 3,000 yr B.P., they may exist, deeply buried in upper reaches of small tributaries. The likelihood of preservation of late Archaic and other late Holocene Plains Woodland and Plains Village sites is much greater, as most valley fill is late Holocene in age. Subsequent removal of late Holocene sites, and further erosion of older cultural components, has most certainly occurred in portions of these small basins due to dramatic lateral migration and channel entrenchment in the last 1,000 years.

A research grant from the Sigma Xi Foundation was provided for this study and is gratefully acknowledged.

Figure 1. Location of Wolf Creek in the Kansas River basin (modified from Johnson and Logan 1990).
Geoarchaeological Reconnaissance for Late Glacial Sites in the Upper Kuskokwim and Holitna Lowlands, Alaska

John F. Hoffecker and Christopher F. Waythomas

During August 1990, we undertook a "geoarchaeological reconnaissance" for late glacial sites in the Upper Kuskokwim and Holitna lowlands of southwest-central Alaska. This type of reconnaissance represents part of a general research strategy based on the systematic application of historical geomorphology to archaeological survey (e.g., Butzer 1960; Hoffecker 1988). The principal objective of the study was to assess the potential of the region for archaeological remains of the late glacial (14,000-10,000 yr B.P.). Preliminary results suggest that some highly promising sedimentary contexts for sites in this time range are present.

Our reconnaissance was focused on two intermontane lowlands in the drainage basin of the upper Kuskokwim River (Figure 1). These lowland basins adjoin the Alaska Range on the south/southeast, and are rimmed by low mountains and rolling hills to the north, west, and east. Today the lowlands are characterized by meandering river channels and extensive tracts of muskeg and bog with localized stands of cottonwood and spruce. Quaternary geologic studies were conducted in these areas by Fernald (1960), Lea (1990), and Waythomas (1990; Lea and Waythomas 1990). These studies indicated that eolian deposits of late Pleistocene age are widespread and well exposed along the many drainages in the region, thus providing a potentially suitable sedimentary context for archaeological remains in this time range. However, the geologic investigations were not undertaken with the needs of an archaeological survey in mind, and it was necessary to assess the archaeological potential of these
deposits. It was also necessary to acquire more detailed knowledge of the late Quaternary stratigraphy and environments of the region.

During the field reconnaissance (August 1-27, 1990), selected localities along the Kuskokwim and Holitna rivers were described and sampled; access to localities was achieved by boat and foot. Two types of localities were examined: (a) those likely to yield useful information on regional stratigraphy and environments, and (b) those likely to represent geomorphic settings with high potential for archaeological remains. At each locality, sediment samples were collected for analysis of granulometry, mineralogy, and fossil biotic contents (pollen/spores, insect remains). All buried organic horizons and tephras were sampled. Samples of aeolian sand, loess, and tephra also were collected for TL dating, while organic horizons were sampled for radiocarbon dating.

The preliminary results of our study indicate that both lowland areas probably possess high potential for late glacial archaeological remains. The most promising geomorphic setting is represented by deep loess deposits that mantle bedrock hills located primarily, but not exclusively, on the north side of the Kuskokwim River. In some places, these deposits occur on south-facing promontories adjacent to tributary streams representing attractive site locations. The massive unbedded appearance, almost complete absence of buried soils, and evidence of thaw-induced reworking and extensive colluviation on lower slopes suggests that the loess accumulated under periglacial conditions, which have not existed in the lowlands since the end of the Pleistocene. It is difficult to account for the thickness of this loess (typically > 2 m) if it is assumed to be primarily of post-glacial age, because local Holocene conditions have not been favorable to loess deposition (i.e., anastamosing suspended-load river, well vegetated surfaces, limited eolian transport). Nevertheless, the late glacial (or earlier) age of these deposits remains to be confirmed by TL dating (see Figure 1b and 1c).

Thick sequences of eolian sediment (sand and silt) lie on the south side of the Kuskokwim River, but represent a less promising geomorphic context for late glacial archaeological remains. Although these deposits, which apparently span much of the late Pleistocene, yield useful information on regional stratigraphy and paleoenvironments (see Figure 1a), they are notably deficient in adequate topographic setting for late glacial sites. The meandering river has eroded the margins of this massive eolian sequence during the Holocene, destroying the low promontories that probably overlooked the Pleistocene floodplain.

Two other geomorphic settings were examined in terms of their potential for late glacial sites. Colluvial deposits described as "creek valley fill" by Fernald (1960:218-219) are exposed at several locations on the north side of the Kuskokwim River. This sediment apparently represents loess reworked from bedrock slopes into tributary stream valleys. However, while the creek valley fill is almost certainly of late glacial (and older) age, it provides little in the way of a topographic focus for archaeological sampling. Alluvial deposits, which occur along the north side of the Kuskokwim in the form of several low
terrace deposits, also were examined. Radiocarbon samples from buried woody peat layers in the highest terrace levels (10-15 m) yielded estimates of 6,020±70 yr B.P. (Beta-60406) and 2,990±60 yr B.P. (Beta-60405), indicating that they are too young to contain situ late glacial remains.

Funding for this research was provided by the National Geographic Society. We also thank the Alaska Geological Survey for the loan of a sixteen-foot Zodiac, and Robert E. Ackerman (Washington State University) for information about the study area, based on his past research.

---

**Figure 1.** Map of the Upper Kuskokwim River area, showing the location of three stratigraphic profiles: A) Big River Bluff; B) Inowak Bluff Site (artifacts recovered from depth of up to 30 cm); and C) Beaver Ridge Site [discovered by Ackerman (1982), who recovered artifacts, including a side-notched point, from depth of up to 15 cm].
Buried Soil Surfaces Beneath the Great Bend Prairie of Central Kansas and Archaeological Implications

William C. Johnson

The Great Bend Prairie of central Kansas, bound on the north by the Arkansas River, is mantled by a sand sheet, from less than 1 to 10 m thick. The sand sheet is immediately underlain by an eolian silt layer containing one or more soils, one of which is always formed within the surface of the silt layer. Backhoe trenches were excavated and drill cores extracted from within the study area in order to describe the stratigraphy and to sample for physical and chemical analysis. At selected locations, soil A horizons were sampled for radiocarbon dating of soil humates (Figure 1). Soils developed within the surface of the silt layer were found to vary from about 13,700 to 800 yr B.P. With the exception of one sample at site 9, all humate ages were determined from the upper 5 cm of the A horizon and therefore represent a minimum age on the soil, i.e., the time

William C. Johnson, Department of Geography, University of Kansas, Lawrence, KS 66045-2121.
immediately prior to burial of the soil. The silt parent material is presently believed to be of Wisconsin (Peorian) age. The ranges in ages of the soil surfaces is, however, likely attributable to prolonged exposure of the silt surface between periodic mobilizations of the sand sheet. Soils buried within the silt layer suggest the silt itself was also mobile.

Although no artifacts have yet been reported from the silt layer, archaeological implications for the Great Bend Prairie are substantial. Most of the soils developed in a well drained environment, but yet the position of carbonates and relative elevation of contemporaneous paleochannels of the Arkansas River and tributaries indicate groundwater was within 2 m of the silt surface. Consequently, water was likely available for wildlife and prehistoric peoples, resulting in a favorable cultural resource base.

The buried soils associated with the silt layer differ in age and duration of development. Based upon soil morphology and radiocarbon data, it appears soil development, and attendant surface stability, persisted from approximately 500 to over 1,000 years. Site 1 dated to 13,670±290 yr B.P. (Tx-6742), designating it a pre-Clovis surface. An age of 5,870±150 yr B.P. (Tx-6478) from the lower 5 cm of the A horizon at site 9 indicates a minimum of 1,000 years for pedogenesis,
all of which falls within the middle and late Archaic period. The age of 17,970±330 yr B.P. (Tx-6479) from spruce (Picea cf. glauca) charcoal below the solum dates the silt parent material. An age of 2,940±80 yr B.P. (Tx-6745) from the soil at site 10 indicates its development took place during the late Archaic period. Trenching at site 7 exposed two well developed soils within the silt. The surface of the silt was last exposed approximately 1,700 years ago, during the Plains Woodland, or early Ceramic period. An underlying soil dated to late Archaic time. A moderately developed soil at site 2 dated to 810±60 yr B.P. (Tx-6743), i.e., pedogenesis during the Plains Village, or Middle Ceramic period.

The limited radiocarbon data indicate at least one surface of pre-Clovis age, three of Archaic age, and one each of Plains Woodland and Plains Village age. A comparison of soil morphology at undated sites with those dated suggests late Pleistocene to middle Holocene surfaces have the greatest areal extent. Therefore, this nearly 2,000 km² area of sand in central Kansas may very well conceal an extensive archaeological record of considerable antiquity.

Preliminary Geoarchaeological Studies of the Sheguiandah Site, Manitoulin Island, Canada

Patrick J. Julig, William C. Mahaney, and Peter Storck

Sheguiandah is a stratified quarry-workshop and habitation site on Manitoulin Island in northeastern Lake Huron. Thomas Lee and John Sanford, the original investigators (see, for example, Lee 1954, 1955, 1956, 1957; Sanford 1957, 1971) describe a sequence of cultural levels (Figure 1). The uppermost deposits contain Woodland and Archaic material. Underlying these deposits is a stratum of fine-grained sediments, possibly of eolian origin (Lee 1957), containing Paleoindian (Easter Plano) projectile points. A single radiocarbon date of 9,160± yr B.P. (W-345) from the basal part of peat deposits in swamp 3, overlying mineral deposits containing artifacts (Lee 1956), was interpreted to be consistent with the late Paleoindian occupation of the site and indicative of yet older occupations, presumably by other cultural groups. Lee and Sanford described two mixed deposits (diamictons) beneath the late Paleoindian stratum, interpreted to be glacial tills. The occurrence of roughly shaped bifaces

in the lower “till” and more finely shaped bifaces in the upper “till” was regarded as evidence for human occupation prior to the onset of late Wisconsin glaciation. Since the initial work, the interpretation of artifacts in “till” has often been mentioned as evidence for pre-Clovis occupation in the New World (Lorenzo 1978; Lee 1986).

Since the work of Lee and Sanford at Sheguiandah in the early 1950s knowledge of the late Pleistocene history of the Great Lakes region has increased considerably. This prompted the senior author to undertake a restudy of some of the artifacts and sediment samples obtained by Lee as a preliminary step to planning renewed excavations at the site. William Mahaney is assisting in the re-analysis and interpretation of the sediment sequence. Recently, Julig, Storck, and Thane Anderson, re-cored swamp 3 in an attempt to obtain material for dating from the basal part of the peat layer and the underlying mineral sediments, which contain organics. It is anticipated that these data will assist in determining the age of some of the sedimentary episodes on the site and the scope of future archaeological/geological fieldwork.

The purpose of this brief report is to present preliminary results of recent particle size and SEM analysis of sediment samples obtained by Lee and Sanford from the so-called habitation area of the site. In addition, several observations are made on possible water-rounded artifacts from the “till” deposits. These data, as well as the sedimentological evidence, provide insights into the geologic origin of the “tills” and the age and cultural affiliation of the artifacts they contain.

Particle Size. Using sediment samples obtained by Lee from four areas of the site particle size ratios of the <2.0 mm fraction were analyzed to determine if any of the deposits have linear curves (non-sorted) suggesting a glacial and/or colluvial origin. Of the 27 samples analyzed from the so-called “till” deposits and underlying sediments, 20 exhibit curves which are characteristic of non-sorted sediment such as colluvium or till. From the “Habitation” area of the site the samples of the sandy gravel over boulder pavement (Figure 1) are sorted and are probably of lacustrine origin. However, detailed fabric analysis in the field and microfabric analysis (Mahaney et al. 1989) in the laboratory should be undertaken in conjunction with scanning electron microscopy of sand subsamples (Mahaney 1990) to assist in determining the origin of the sediments. From these initial analysis the so-called “till” deposits are clearly non-sorted and may be till, or colluvium, or possibly the result of storm beach processes during a high water phase (Early Mattawa flood) during early post-Lake Algonquin times (Lewis and Anderson 1989).

Scanning Electron Microscopy. Quartz grains from the fine and very fine sand fractions (63-250 µm) from deposits in the habitation area that Lee interpreted to be glacial were analyzed for surface features. The results indicate a mix of old fractured and well-weathered grains that were likely preweathered and/or reworked from older deposits. No evidence of fresh glacial-crushing effects or abrasion were observed on any of the grains studied. Some quartz grains in the upper “till” (diamicton) had sawtooth fracture patterns that have been observed on sub-aqueous marine debris flow deposits (Mahaney
Figure 1. Topographic profile and representative stratigraphic sections from Sheguiandah site, Manitoulin Island, Canada.
unpublished). Crescentic gouges (Krinsley and Doornkamp 1973) which are widely considered to be the effect of transport by continental ice, were also observed on grains of several samples. Some rounded grains of quartz were found in all samples. Some rounded grains of quartz were found in all samples studied but all were weathered to some degree. Even fragments with deep-furrow features, presumably originating from transport in continental ice, showed weathering effects, mainly as dissolution etching (Mahaney et al. 1988). The lack of fresh crushing in these samples suggests they may not have been transported to the Sheguiandah site as a result of transport by continental ice.

Waterworn Artifacts. During the analysis of artifacts a number of possible water-rounded specimens were examined, including both tool fragments and flakes. Certain of these had significant rounding and smoothing of lateral margins and flake scar ridges, which may indicate that the site was affected by a post-occupation flooding episode, however this clearly requires further investigation.

Future Research. Further excavations and a range of sedimentary analyses are clearly required to resolve the complex geological problems at this complex site. Organic samples from the base of the peat and wood and plant fragments from the underlying mineral sediments in swamp 3, obtained in the recent coring, have been submitted for AMS \(^{14}\)C dating. Further excavations are planned in 1991.

The authors would like to thank Dr. Thane Anderson of the Canadian Geological Survey for his participation in this project. Field expenses connected with the recoring of swamp 3 were partly funded by the Royal Ontario Museum. The support of the Social Science and Humanities Research Council of Canada for ongoing Sheguiandah site research is gratefully acknowledged by the senior author.

Applications of Quaternary Surficial Mapping to Archaeological Investigations in British Columbia, Canada

Dan E. Kerr, Vic M. Levson, and Chris P. Smith

Surficial mapping projects of Pleistocene deposits are routinely conducted by Quaternary geologists. Paleoenviromental reconstructions and inferred suitability for habitation by man can be compiled for each mapped terrain unit. These data can by utilized to focus archaeological surveys on terrain units with the greatest potential for Pleistocene archaeological sites. Therefore, this survey procedure would be preferable to random grid survey techniques. A recent Quaternary mapping program was initiated in British Columbia (BC) in 1990 and the results of this program and implications for archaeological studies of Pleistocene sites are discussed here to exemplify the potential utility of this procedure. Published data on Pleistocene and early Holocene archaeological sites are lacking in this region of British Columbia (Bobrowsky et al. 1990). However, environmental impact assessments and archaeological surveys are planned in many areas due to mining developments. Archaeological investigations would be expedited by focussing on terrain units of high

Dan E. Kerr, Vic M. Levson, and Chris P. Smith, Quaternary Research Group, Department of Geology, University of Alberta, Edmonton, AL, T6G 2E3.
potential, as exemplified here for one of BC's most active areas of mineral exploration.

The mapped area (Kerr 1991) is in central BC, 150 km north of Prince George. The area lies in the Omineca Mountains and is characterized by a boreal forest vegetative cover and abundant wildlife. Figure 1 illustrates a representative portion of the mapped area. The area was glaciated during the last glacial episode (late Wisconsin). Ice-flow indicators such as drumlinoids and striae suggest a southwest to northeast direction of ice advance across the area, with only minor changes in flow direction on a local scale. Regional mapping indicates a complex deglaciation pattern with glaciolacustrine ponding and sedimentation along some valleys. Paleocurrent directions from glaciofluvial sediments laid down during deglaciation (Figure 1) show a general trend to the northeast. Ice had completely disappeared sometime before 10,000 yr B.P. (Clague 1989). Evidence for human occupation between 10,700 and 10,100 yr B.P. has been documented at the Charlie Lake Cave site, about 225 km to the northeast of the map area (Fladmark et al. 1988; Driver 1988).

Figure 1. Surficial geology of the Heidi Lake area, central British Columbia, Canada. Large arrow indicates ice flow direction. Small arrows show paleoflow directions in glaciofluvial deposits. Hachure symbols identify eskers. Mapped terrain units are described in the text.
The surficial deposits, which may attain tens of meters in thickness, consist mainly of matrix-supported diamictons in the form of a till blanket (Mb on Figure 1), as well as glaciofluvial deposits of sand and gravel (F^G). The latter generally exhibit a southwest-northwest trend as defined by sinuous esker ridges and broad outwash plains; the dominant meltwater paleocurrent direction obtained from outwash sediments is to the northeast. Till veneer (Mv) and colluvium (Cv, Cb) frequently mantle the steeper slopes of hills and valleys. Organic deposits (O) locally overlie fluvial or lacustrine sediments. To the east of the area shown in Figure 1, isolated deposits of glaciolacustrine fine sand, silt and clay are found within several topographic depressions.

Terrain units with the greatest potential for discovery of Pleistocene archaeological sites include littoral zones of some fluvial and lacustrine units. During the late Pleistocene lake basins and river channels were generally more extensive than at present. Low lying portions of these units are locally overlain by organic deposits and paleo-shorelines typically lie at higher elevations. Although mainly occurring in the Holocene, some fluvial and lacustrine deposition may date to the late Pleistocene. High fluvial terraces, raised beach ridges and perched deltas are the best targets for detailed field surveys. Esker ridges would have been ideal vantage points for spotting game. The ridges were well drained and may have been preferred sites for both humans and large mammals migrating through the area. Eskers are still preferred migration routes for caribou in the Canadian Arctic, and deer and other large mammals commonly utilize these terrain features in the map area.

Paleoenvironmental interpretations of glaciofluvial and glaciolacustrine units indicate generally unfavorable conditions for aquatic flora and fauna due to high sedimentation rates, high turbidity and low water temperature. However, due to good drainage and proximity to water, these areas may have been preferred over poorly drained morainal units, by early peoples inhabiting or migrating through these recently deglaciated areas. Within these broad map units, sites with the greatest potential include glaciofluvial terraces, deltas, and sandy glaciolacustrine littoral units.

Late Pleistocene-Early Holocene Soil-Sediment Relationships on the Kersey Terrace, Northeastern Colorado

Michael McFaul, William R. Doering, and Christian J. Zier

The Kersey terrace of the South Platte River at Kersey, Colorado, is one of the most well-known Paleoindian locales on the Great Plains. Sites and isolated finds on the terrace and vicinity exhibit materials from Llano, Folsom, and Plano complexes. Proposed highway construction resulted in an examination of terrace soils/sediments along 8 km of US 34 as well as those at Klein II, Fox, 5WL48, 5WL1555, and Frazier sites. A 50-m-interval soil-coring program paralleling the highway right-of-way and an examination of natural exposures defined the extent and characteristics of the soils/sediments. Additional soil/sediment analysis and dating is on-going.

The Kersey terrace, which is correlated with the late Pleistocene Broadway terrace upstream in the Denver vicinity (Scott 1963; Smith et al. 1964; Colton 1978), is considered the oldest of three alluvial terraces in the area (Holliday 1987). At Kersey, the terrace is a broad (3 km wide), low-relief surface about 12 m above the South Platte River.

Basal terrace sediments are moderately-sorted, quartz and granite-rich channel sands and gravels derived from the Rocky Mountains. These sediments were deposited in the late Pleistocene across a braided network. Forms indicative of braided conditions include numerous low-relief gravel bars and abandoned channels.

Clovis artifacts were found in the upper Kersey gravels at the Klein II site and at other scattered localities. The absence of post-Clovis artifacts within the gravels indicates that braided deposition ceased after 11,000 yr B.P. The association of these artifacts with gravel ridges suggests these Clovis groups used the ridges to traverse the braided network (Louis Klein, pers. comm. 1990).

Fine-grained and thin-bedded overbank alluviation replaced braided deposition after 11,000 yr B.P. Radiocarbon dating of the organics in the upper
12 cm of these sediments at 5WL1555 suggests that overbank alluviation continued through 8,637±130 yr B.P. cal (Beta-40751; Stuiver and Reimer 1986). Indicators of a high water table within the fine-grained sediments imply that prior to 8,637 yr B.P. the South Platte River had not yet abandoned the terrace. This evidence includes an Aquoll with: 1) an organic-rich soil A horizon, 2) a gleyed soil B horizon, and 3) iron and manganese staining.

Continued overbank deposition, possibly augmented by eolian sedimentation from the adjacent river channel, resulted in burial of the Aquoll (≤8,637 yr B.P.). A well-developed Argiustoll with strong prismatic structure developed in these sediments. Subsequent erosion and/or agricultural practices (e.g., leveling, plowing) has removed the epipedon of this soil.

A re-examination of soils/sediments at the Frazier site, described by Malde (1988), suggests that the buried A horizon (Aquoll) and the overlying Bt horizon (Argiustoll) correlate respectively with his “gley layer” and “prismatic clay”. Bison (Bison) bone and artifacts that include Agate Basin projectile points (ca. 10,500-9,500 yr B.P.) were recovered from the lower “prismatic clay". However, we disagree with: 1) the use of the term "gley layer", 2) the proposed eolian origin of the sediments in the “prismatic clay”, and 3) the statement that the “gleyed layer” has no recognized counterparts upstream.

On the contrary, we find evidence that the soil/sediment relationships at the Frazier site occur elsewhere on the Kersey terrace. Furthermore, the existence of the Aquoll at numerous localities across the Kersey terrace and a similar-aged soil in dune sediments at Hudson, Colorado (Forman and Maat 1990) suggests that the Aquoll is a floodplain member of a regional, late Pleistocene-early Holocene pedoderm rather than a site specific phenomenon.

Late Pleistocene-Early Holocene Paleoclimates and Environments of Southwestern Montana.

Mort D. Turner, Marvin T. Beatty, Murray Klages, Paul McDaniel, Joanne C. Turner, and Robson Bonnichsen

Geoarchaeology of a Pleistocene/Holocene archaeological site in southwestern Montana, the Everson Creek/Black Canyon Quarry Complex (Bonnichsen et al. 1990a,1990b; Turner et al. 1988) shows that major and abrupt shifts in climate occurred at the Pleistocene/Holocene boundary, about 11,000 yr B.P. (Birkeland et al. 1971; Locke 1990; Turner et al. 1988). Dating of this episode is constrained by archaeological data, $^{14}$C dates, and rates of deposition. There is evidence of massive flood(s) occurring over a relatively short period of time, from a year to several tens of years, during this climatic episode. South Fork Everson Creek is presently about 1 m wide and 10 cm deep. Our data show that flood-plain flow occurring before and after the climatic episode at 11,000 yr B.P. had a grain-size-carrying-capacity of less than 3 mm in diameter. Thus, the stream flow could move only very small particles of rock. However, flood(s) occurring at the time of the climatic episode, approximately 11,000 yr B.P., were much larger, causing deep erosion in parts of the Pleistocene flood plains and concurrently depositing sediments over 1 m thick that contain transported boulders of up to 50 cm in diameter. This indicates that stream flow during these large floods increased several thousand times in volume over stream flows prior, and subsequent to, the end of the Pleistocene.

Evidence for a major environmental change and several lesser environmental alterations comes from the presence of a strongly developed paleosol within the strata of the Cody workshop floor, and from the presence of three paleosols above it. These paleosols are weakly developed morphologically but show noticeable enrichment with organic matter when compared to horizons which overlie and underlie them (Soil Survey Staff 1975, 1981). Most significant is an
abrupt change in clay-mineral species above and below the Cody workshop paleosol. Clay in and below this paleosol is dominantly vermiculite; above this soil, the smectite clays dominate. The paleosol has strong prismatic peds coated with clay argillons and organic stains which are on the tops and upper sides of the peds. It has many of the morphological characteristics of a natrargid (Soil Survey Staff 1975, 1981) but has been leached of exchangeable sodium, soluble salts, and calcium carbonate. The morphology of this soil suggests a much drier climate at the time of intense human use that led to development of a rich assemblage of Cody workshop-floor artifacts about 9,400 yr B.P. (AMS date on charcoal, 9,390±90 yr B.P. (TO-1976)).

Two charcoal samples from hearths in upper levels of the Mammoth Meadow sequence were dated by 14C at 1,830±90 yr B.P. (Beta-40580) (Level IE, 50-60 cm) and 490±50 yr B.P. (Beta-37608) (Level IC, 49.8 cm). For Level relationships see diagram of composite vertical section of site (Bonnichsen et al. 1990a).

The soil chemistry of this paleosol suggests a much drier climate. The clay minerals in the section relate strongly to bedrock sources for the soils in which the minerals occur (Klages and Montagne 1985; Montagne et al. 1982), because weathering of clay-size layer-silicate minerals in soils in Montana is minimal. Thus, the distinct change from vermiculite clays below the Cody workshop paleosol to smectitic clays in the loess and paleosols above it indicates a distinct and important change in source materials for the deposits entering the valley of South Everson Creek.

Vermiculite in clay-size soil fractions from this area is typically derived from rock types of the Belt series, a pre-Cambrian metamorphic complex that forms the core of the mountains to the northwest of the site (Staatz 1979; Turner et al. 1988). Thus, while late Pleistocene glaciers were actively eroding Belt Series rocks in the mountains, finely-ground rock dust (silt) produced by this erosion was being laid down on flood plains below the foot of the glaciers. Pedogenic processes converted some of these sediments to vermiculite. Subsequently, but still during the Pleistocene, these silts and clays were picked up by winds blowing southeastward and deposited as loess across the area that includes the archaeological site.

Smectite in the site area is typical of clay minerals derived from soils and sediments younger than the Belt Series and associated with the Laramide Revolution (Cretaceous) to Present. Such sediments are primarily Tertiary-age lake beds that lie largely to the north and northeast of the site (Nichols 1988). The occurrence of smectite shortly after the close of the Pleistocene and throughout the Holocene, indicates a rapid increase in temperature and lower precipitation. This caused a loss of vegetation cover in the basins and dried up the Tertiary lake beds northeast of the site, and exposed them to wind erosion. The climatic changes also included a shift of wind patterns, so that dust and smectite clay from the basins in the north and east were transported to the site area, depositing them as loess.

Lying between the Pleistocene loess and the Holocene loess is the natrargid paleosol/Cody workshop-floor soil. This paleosol is indicative of drier
conditions and alkaline water near the pedogenic surface. Additional scientific project data are being developed to determine if major changes in flora, fauna, and human culture also occurred in site area at this time.

We conclude from our evidence, presented above, that a major environmental/ecological shift occurred in southwestern Montana at the end of the Pleistocene, and that lesser shifts occurred both prior and subsequent to the major shift described herein. An intense climatic event with very high precipitation took place at or near the time of this major Pleistocene/Holocene climatic shift.

Late Quaternary Fluvial Activity and Climate Variability in the Colorado Front Range Foothills and Piedmont

C.E. Waythomas, R.D. Jarrett, and W.R. Osterkamp

Research has been initiated in the Colorado Front Range foothills and piedmont region to explore the relations between latest Pleistocene and Holocene river behavior and climatic variability. Recent large floods in the Western United States (e.g., Big Thompson River, Colorado, 1976; Rapid City, South Dakota, 1972; Swift River, Montana, 1964) have focused attention on the temporal aspects of floods and their potential relation to aberrations in the climate system. To understand the significance of such large-magnitude flood events, one must place them in an appropriate geomorphic context that can explain their temporal and spatial occurrence. The goal of our research in Colorado and other western states is to establish a linkage between climate and river response using data derived from study and dating of alluvial stratigraphic records. Such information can be used to develop better predictive models involving anticipated climatic variation and associated changes in the hydrologic system. The research is expected to provide new data about late Quaternary flood frequency and magnitude, the chronology of geomorphically significant fluvial events, and paleohydraulic conditions. Locally, the results will serve as an extension of the historic record.

Fluvial deposits and their associated landforms in several geomorphic settings are being studied. In the mountainous foothill belt of the Colorado Front Range, the principal record of Holocene fluvial activity consists of coarse-grained flash-flood deposits and minor debris-flow deposits (Bradley and Mears 1980; Costa 1983). Typically, these deposits are well preserved along steep bedrock channels, where they form longitudinal boulder bars of berms (Carling 1987). Field studies have documented the deposit geometry and sedimentology by using measurements of clast orientation, particle size, and weathering characteristics. These data also are useful for differentiating water-flood deposits from debris-flow and other deposits formed by mass-wasting. Wood samples for radiocarbon dating have been collected from many...
flash-flood deposits. These results are expected to provide chronological control on flood events in the region.

Selected localities where bouldery flash-flood deposits are well preserved have been chosen for paleohydraulic reconstructions of flow competence (bed shear stress, unit stream power) and discharge using the step-back water approach (Baker and Costa 1989; Carling 1983; Chow 1959; Costa 1983; Henderson 1966; Komar 1989). At these locations, channel cross-section dimensions and altitudes of paleostage indicators are surveyed. Paleodischarge and flow competence estimates are made from representative cross-section data, estimates of bed-roughness, and particle-size measurements. Preliminary results from Arthurs Rock Gulch, an ephemeral stream tributary to a large municipal reservoir west of Fort Collins, Colorado, indicate that peak flood flows have decreased in magnitude throughout the Holocene. However, in other basins in the Front Range foothills, some of the largest known floods have occurred in the last century (e.g., 1976 Big Thompson flood; McCain et al. 1979).

In addition to studies of bouldery flash-flood deposits in steep bedrock canyons, fine-grained alluvial deposits preserved along rivers and tributaries of the Colorado Front Range piedmont are being examined. In this region, Holocene alluvial deposits (e.g., Piney Creek alluvium) appear on most geological maps; however, information about the age, sedimentology, and environmental significance of these sediments is lacking. Typically, Holocene alluvial deposits in the study area consist of 5- to 10-m thick sequences of massive- to horizontally-bedded overbank sediments that contain numerous buried soil horizons and organic matter suitable for radiocarbon dating. Bounding surfaces between sedimentation units commonly represent minor unconformities and are usually denoted by sharp contacts or buried soil horizons that are readily identifiable in the field. These relations permit identification of episodes of overbank flood deposition. At some locations (e.g., Plum Creek near Sedalia, Colorado), as many as 15 episodes of Holocene flooding have been recognized.

The objectives of our studies of Holocene alluvial deposits are to (1) establish a detailed, high-resolution chronology of flood events from areas in eastern Colorado, as well as other localities in the Western United States, (2) document the fluvial sedimentologic and geomorphologic relations of latest Pleistocene and Holocene deposits in these areas, and (3) provide paleohydrologic information that may be useful in extending existing systematic and historic records. This information can be compared to proxy records of Holocene climatic variation (pollen, fossil insects, tree rings, glacier fluctuations) to develop an understanding of the possible linkages between climate and river behavior (e.g., Knox 1983; Schumm and Brackenridge, 1987).

Bathymetry and Stratigraphy of Wonder Lake, Alaska

Al Werner

The Muldrow Glacier invaded Wonder Lake (63°30'N, 150°50'W) three times during the late Wisconsin; the north end of the lake is dammed by the glacial limit, the south end of the lake is dammed by a younger stadial moraine, and a moraine of intermediate age occurs midway in the basin (Werner 1982).

Twenty six transverse and longitudinal bathymetric profiles were measured with an acoustic "fish-finding" device, and digitized to produce computer maps. These data refine the bathymetry presented by LaPerriere and Casper (1976). Wonder lake is relatively shallow (<10 m) at both north and south ends, but reaches a maximum depth of 78 m in the deep main basin (Figure 1). The lake basin has a classic "glacial trough" morphology with steep sides and a broad flat bottom. An east-west trending bathymetric ridge separates a northern basin from the deep main basin.

An acoustic sub-bottom profiling device was used to document the stratigraphy along 20 transects. The resulting profiles were digitized and computer isopach maps were produced (Figure 1). Three main sedimentary units are recognized in the lake basin; a northward thickening (7 m) sediment wedge at the north end of the lake, a thick (25-30 m) layered unit at the south end of the lake, and a 4-6 m layered sediment unit in the deep main basin. The sediment wedge at the north end of the lake indicates a northerly sediment source (i.e., the modern inflow stream). Although the modern stream is small, during deglaciation it served as a meltwater stream along the glacial limit. during glacial retreat, meltwater would have emptied into Wonder Lake before draining to Moose Creek. According to this model, the unit immediately post-dates the glacial maximum.

The thick sediment wedge at the south end of the lake (thickening southward) is associated with the moraine damming the south end of the basin. The well-layered stratigraphy is consistent with a meltwater origin, and is correlated with an outwash fanhead on the east side of the lake. The notable thickness of this unit suggests the glacier maintained this position for a relatively long time.

Of greatest interest is a layered unit in the distal deep main basin. The banded stratigraphy indicates changing sedimentological conditions interpreted as glacial advance and retreat. Wonder Lake is currently "sediment-limited", but sedimentation would have changed abruptly when the
Muldrow Glacier entered (and retreated from) the basin. The number of acoustic layers in the basin fill is consistent with the number of stadial moraines (and interstadial periods) recognized in the valley.

Figure 1. Bathymetry (1a) and sediment isopach (1b) maps of Wonder Lake. Lake basin is 1.0 by 4.5 km.

Information for Contributors

GENERAL INFORMATION
Categories of notes will be: 1) Archaeology, 2) Physical Anthropology, 3) Lithic Studies, 4) Taphonomy-Bone Modification, 5) Methods, 6) Paleoenvironments (which includes the subsections: Plants, Invertebrates, Vertebrates, and Geosciences), and 7) Special focus. The last category is reserved for a pre-selected topic; articles are submitted by authors at the request of the Center. Usually no more than 65 unsolicited papers for the regular sections and 5 solicited papers for the Special Focus section will be accepted. No more than 2 papers will be accepted from any one senior author. Time being of the essence, the earlier a paper is received, the better its chance of being published. Manuscripts concerned with any of the above categories should include research dating ≤10,000 yr B.P. or have direct implications for research of that time period.

Manuscripts should be of note length, ≤1000 word, or 400 words with one figure and caption, plus references. They should be current, original, not be or have been submitted to another journal, and may cover any aspect of the above-mentioned categories. All notes will be published in English. Authors submitting manuscripts in a language other than English may either submit their manuscript also in English or request the editorial staff to provide a translation (final decision will be left to the editorial board). In either case, both accepted manuscripts will be published. Manuscripts submitted in a language other than English should be typed double-spaced throughout and be legible. If a manuscript requires extensive editing or if a meaning is unclear, the author will be contacted—this could delay the printing of the manuscript.

Manuscripts are first read by the editorial staff to ensure the minimum requirements are met, as outlined above. All manuscripts are edited for style and general grammar. Because one of the practical goals of the journal is to provide quick turnaround time for the printing of manuscripts, authors do not review galley or page proofs. The editor staff compares the submitted manuscripts with the style-edited page proofs. Thus it is imperative that authors carefully proof their manuscripts for content, journal style, and grammar. It is suggested that all manuscripts be reviewed by a colleague of the author prior to submission. All manuscripts receive peer reviews.

FORM AND STYLE
Manuscripts should be concise but detailed enough to permit critical appraisal. They must be typed and DOUBLE-SPACED THROUGHOUT (i.e., entire
Information for Contributors

Manuscript, references, and figure caption) on one side of 22 by 28 cm (8-1/2 by 11 inch) paper with no less than 4 cm (1-1/2 inch) margins.

If a word processor is used, use the following specifications in preparing and printing your manuscript. Use letter quality or near letter quality printing. Align text to the left margin only—do not justify. Underline any words that should be italicized in the final typeset galleys. DO NOT hyphenate words at the right margin. Manuscripts should be submitted in both printed form and on computer disk (Macintosh, MS DOS/IBM, or Apple II format). In addition to the original word processing document, the disk should also contain an ASCII version. The computer will probably be able to translate the text and formatting from the original document, but if it can't translate the original, it will at least be able to read the ASCII file. Manuscripts that conform to these specifications will allow us to fully utilize the technology we have available in preparing manuscripts for publication, to keep both the turnaround time, and the cost of the journal down.

Space will not permit the inclusion of tables. Materials that normally would be placed in a small table should be placed in the text [(e.g., "There are five radiocarbon dates from this site (15,000±100 yr B.P. (A-000),...11,000±100 yr B.P. (A-0000))").] One figure is permitted; the caption should be typed on a separate page using all the above-mentioned specifications for text preparation. All pages should be numbered consecutively starting with the first page of text. The title page should include an informative title, author(s), affiliation(s), and complete mailing address(es), which must contain your zip code or postal district, when applicable. It would help to include your telephone number and your BITNET number, if possible, on your cover letter, should there be any questions by the editor. Avoid titles with interrogative form, abbreviations, and formulae. Submit three (3) copies of each manuscript and at least one PMT or glossy print of the figure, if one is included. Authors should keep original art.

Standardized words or spellings that do not need to be underlined or described: in situ; et al.; pers. comm.; Paleoindian; archaeology; CRM (for cultural resource management); MNI (for minimum number of individuals); TL (for thermoluminescence dating); yr B.P. (for years before present); and AMS or TAMS (for accelerator mass spectrometer technique of radiocarbon dating). Do not italicize words in the manuscript, only underline (Ficus not Ficus). The use of either Latin or common names is fine, but include the other (common or Latin) name in parentheses following the first time use (e.g., "...recovered the dung of the Shasta ground sloth (Nothrotlzeriops slzastensis)"). If technical jargon or abbreviations are to be used, and possibly are not well known to all readers, provide a more common term or explanation in parentheses.

UNITS AND ABBREVIATIONS

Metric units should be used throughout and be abbreviated when appropriate. Examples of the abbreviation style used include: i.e.; e.g.; cf.; cm; m; km; ha; yr B.P.; and sp. Numbers will be written out when they start a sentence or when they are the numbers one through nine (exception: "...20 choppers, 10 burins, and..."
2 knives were recovered.") numbers greater than nine are written as numerals (e.g., 10, 11, 1,000). All numbers greater than 999, including radiocarbon ages, should use a comma 22,200-1,210 yr B.P.; 1,000 years ago; 12,000 mollusks).

Radiocarbon dates should be expressed in $^{14}$C years before present (yr B.P.) and should include the standard error and the laboratory number (e.g., 11,000±140 yr B.P. (A-1026)). International notation should be employed in all cases of chemical notations.

Illustrations

If a figure is used, it must be cited in the text; e.g., "...as can be seen in Figure 1.," "...as is illustrated (Figure 1)." Line drawings ONLY (no color or continuous tone photographs). Submit at least one glossy photographic or PMT print of the figure, 10 by 12.5 cm (4 by 5 inch) maximum image size. Photocopies and Polaroids are not acceptable quality for reproduction (because they are often gray—not true black as needed). Do not send the original artwork.

All lettering MUST be either mechanical or dry transfer (NO HAND LETTERING or TYPEWRITER LETTERING). Authors should check the figure prior to submission to assure that all lines and lettering are clear and legible. The editorial staff and the printers of the journal are not responsible for reduction quality or figure retouching. The senior author’s name should be clearly printed on a label and affixed to the back of the figure.

References Cited

References cited in the text must adhere to the format printed in this edition of CRP. DOUBLE SPACE ALL REFERENCES. Citing in the text is as follows: "...according to Martin (1974a, 1974b)," "...as has been previously stated (Martin 1974; Thompson 1938)." Cross check all references with the original work—this is where most problems occur.

Deadline

Manuscripts MUST be postmarked no later than January 31 of each year. It is strongly suggested that manuscripts be submitted prior to the deadline.

Submit manuscripts (three copies and computer disk file) for Volume 9 (1992) to:
